Factors Affecting Anion Movement and Retention in Four Forest Soils

DALE W. JOHNSON, DALE W. COLE, HELGA VAN MIEGROET, AND F. W. HORNG

ABSTRACT

Three hypotheses concerning the movement and retention of anions in forest soils were tested in a series of laboratory and field studies on two Tennessee Ultisols with mixed deciduous forest cover and two Washington Inceptisols, one with deciduous (red alder Alnus rubra Bong.) and one with coniferous [Douglas-fir, Pseudotsuga menziesii (Mirb.) Franco) forest cover. The first hypothesis, that sulfate and phosphate retention was related to adsorption to free Fe and Al oxides, was not supported by field and laboratory studies. The young, relatively unweathered Washington Inceptisols adsorbed more phosphate and sulfate than the older, highly weathered Tennessee Ultisols, apparently because of greater amorphous (oxalate-extractable) Fe and Al in the former. The second hypothesis, that NO₃ retention was governed primarily by biological uptake, was supported. Nitrate adsorption by soils in laboratory column studies was negligible, but subsequent field studies showed that tree uptake in field plots greatly reduced the leaching of applied NO₃ in all but the N-rich red alder plot. The third hypothesis, that inputs of mobile anions will reduce pH and concentrations of bicarbonate and adsorbing anions (e.g., sulfate), were supported by application of chloride as both acid and Na and Ca salts to soil columns in the laboratory. Sulfate concentration as well as bicarbonate concentrations in soil solutions were sensitive to solution pH.

Additional Index Words: bicarbonate, NO₃, SO₄, chloride, phosphate, adsorption, uptake, leaching.

Nye and Greenland (1960) first suggested that leaching in forest soils is limited by a lack of mobile anions in the soil. According to this concept, leaching cannot occur without an anion (or anions) to maintain electrochemical neutrality in soil solution. Cole and Gessel (1965) and McColl and Cole (1968) first applied Nye and Greenland’s concept to describe carbonic acid leaching in undisturbed, fertilized, and harvested conditions in a forest soil. Subsequent studies confirmed the important influence of anion pro-

[\text{solution phase}, \ C = \text{cation}, \text{ and } r = \text{valence of cation.}]

Solving for \( H^+ \), we have

\[
[H^+] = \left( \frac{[H^+][C^{r+}]}{(C^{r+}) Q} \right)^{1/r}
\]  

[2]

This equation shows that we can change soil solution \( \text{pH} \) by changing exchangeable \( (H^+) \) or \( (C^{r+}) \) (e.g., by changing base saturation) or by changing solution cation concentration, \( (C^{r+}) \). Generally, the pool of exchangeable cations or \( H^+ \) per unit of soil is much greater than the pool of solution cations of \( H^+ \). Thus, changes in base saturation are more difficult to produce and longer in duration than those in solution concentrations, and for our purposes it is useful to separate the two into long- and short-term effects.

Since chloride is relatively unaffected by either biotic or abiotic chemical reactions in soils, it normally leaches through soils without reaction. However, the input of any mobile anion (such as \( \text{Cl}^- \)) should result in a short-term lower soil solution \( \text{pH} \) whether the anion is input as a salt or as an acid. This is because the concentration of cations \( [C^{r+}] \) will be elevated concomitantly with the concentration of the introduced anion in soil solution, and this will in turn elevate \( [H^+] \) according to Eq. [2]. In the case of an acid input, \( H^+ \) will displace exchange cations, lowering base saturation, and in this way induce a long-term decrease in \( \text{pH} \) and total ionic leaching following the passage of the initial flux. In the case of a salt addition, there should be some \( H^+ \) displacement by incoming cations (by mass action), resulting in a long-term increase in base saturation, \( \text{pH} \), and total ionic leaching following the initial flux. Thus, although \( \text{Cl}^- \) (or any other mobile anion) itself may pass through the soil unaffected, it can have both short- and long-term effects on the mobilities of other anions and on total ionic flux.

As a result of the considerations outlined above, we constructed the following hypotheses concerning anion mobility in forest soils:

**Hypothesis I:**

The mobility of sulfate and phosphate in soil is related to the free \( \text{Fe} \) and \( \text{Al} \) content of the soil which, in turn, is a function of the original chemical composition of the soil and the degree to which it has been weathered.

**Hypothesis II:**

The mobility of \( \text{NO}_3^- \) is controlled by biological uptake rather than abiotic chemical processes.

**Hypothesis III:**

Although mobile, biologically inactive anions such as \( \text{Cl}^- \) will pass through the soil unaffected, the additions of such anions as salts or acids will have both short- and long-term effects on soil solution \( \text{pH} \) and on the mobilities of other anions, thus effecting an increase or decrease in net ionic flux from the soil.

These hypotheses were tested in a variety of laboratory and field experiments on two Ultisols with mixed deciduous forest cover in eastern Tennessee and two Inceptisols, one with coniferous \( \text{Douglas-fir}, Pseudotsuga menziesii \) (Mirb.) Franco and one with deciduous (red alder, \( \text{Alnus rubra} \) Bong.) cover in western Washington. Results of these tests are summarized in this paper.

**SITES**

**Walker Branch Watershed, Tennessee**

Walker Branch Watershed is situated in the ridge and valley physiographic province near Oak Ridge, TN (Grigal and Goldstein, 1971). The climate type is humid mesothermal with moderate summer and winter temperatures. Mean annual temperature is 14.3°C and precipitation averages 151 cm/yr, mostly as rain (Henderson et al., 1977). Soils of the watershed are primarily Ultisols derived from Knox dolomite, a cherty, dense to coarsely crystalline rock of late Cambrian to early Ordovician age. Soil coarse fractions consist of chert, Fe-Mn nodules, and quartz. Clay fractions consist primarily of kaolinite with lesser amounts of vermiculite, hydrous micas, and quartz, (Peters et al., 1970). In a nearby site with similar parent material, Lee et al. (1984) concluded that kaolinite was weathering to \( \text{Al} \) hydroxy-interlayered vermiculite in surface horizons.

The chestnut oak \( (Quercus prinus \ L.) \) stand on Walker Branch is located on a ridgetop on the Fullerton series soil, a Typic Paleudult. Coarse fragments range from 30% in E horizons to 17 to 18%, in Bt horizons and clay content ranges from 3 to 12% in E horizons to 40 to 50% in Bt horizons (Peters et al., 1970). Vegetation type is chestnut oak, described by Grigal and Goldstein (1971). Species consist primarily of chestnut oak; mixed deciduous (\( \text{Acer rubrum} \ L.) \), white oak \( \text{(Quercus alba} \ L.) \), black oak \( \text{(Q. velutina} \ L.) \), black gum \( \text{(Nyssa sylvatica} \ Marsh.) \), sourwood \( \text{(Oxydendrum arboreum} \ L.) \), and yellow-poplar (\( \text{Liriodendron tulipifera} \ L.) \), with occasional dogwood \( \text{(Cornus florida} \ L.) \) and northern red oak \( \text{(Q. rubra} \ L.) \). Understory is absent.

The yellow-poplar stand is located in a sinkhole depression on the Tarldin series soil, a Typic Fragudult. Coarse fragments range from 7% in Ap horizons to 12 to 17% in Bt horizons and clay content ranges from 4 to 7% in Ap horizons to 12 to 17% in Bt horizons (Peters et al., 1970). Vegetation type is yellow-poplar, described by Grigal and Goldstein (1971). Species consist primarily of yellow-poplar with occasional red maple, white oak, black locust \( \text{(Robinia pseudacacia} \ L.) \), persimmon \( \text{(Diospyros virginiana} \ L.) \), black cherry \( \text{(Prunus serotina} \ Ehrh.), and Carolina buckthorn \( \text{(Rhamnus caroliniana} \ D.C.) \). Understory consists of dogwood, occasional eastern red cedar \( \text{(Juniperus virginiana} \ L.) \), and Japanese honeysuckle \( \text{(Lonicera japonica} \ Thunb.) \).

**Thompson Site, Washington**

The Thompson site is located in the western foothills of the Cascade Mountain range, Lan­dsburg, WA. The climate type is maritime with cool, dry summers, and wet, moderate winters. Mean annual temperature is 9.8°C and mean annual precipitation is 136 cm, most of which falls as rain between October and March. The soil at the study site belongs to the Alderwood series, a Dystric Entic Durochrept, and is composed of loosely consolidated ablation till of varying depth over a compacted basal till. Brackett (1966) found a predominance of quartz and feldspar with lesser amounts of chlorite, plagioclase, and chaledony in the very fine sand fraction of this soil. The predominant clay mineral was found to be vermiculite.

The research plots are located in a naturally regenerated 48-yr-old stand of red alder and in an immediately adjacent 48-yr-old plantation of Douglas-fir. The understory in the
red alder stand is dominated by sword fern [*Polystichum munitum* (Kauf.] Presl.) intermixed with occasional western hemlock [*Tsuga heterophylla* (Raf.) Sarg.], huckleberry (*Vaccinium parviflorum* Smith), vine maple (*Acer circinatum* Pursh.), Oregon grape [*Berberis nervosa* (Pursh.) Nutt.], and elderberry (*Sambucus callicarpa* Pursh.). Understory in the Douglas-fir stand is much less predominant and consists of salal (*Gaultheria shallon* Pursh.), Oregon grape, huckleberry, and mosses.

**METHODS**

**Field Studies**

At each of the four study sites, four 6- by 6-m plots were laid out. At Walker Branch, a soil pit (approximately 0.5 by 0.75 m at the surface) was dug in the center of each plot; at the Thompson site, a larger soil pit (approximately 1 by 2.5 m at the surface) was dug between pairs of plots. Soil samples were taken proportionally by horizon (i.e., a column of soil was taken from the entire horizon depth) from the pit walls prior to lysimeter installation. Soils were analyzed for a number of chemical and physical properties (Johnson et al., 1981). Those relevant to this study included pH (1:1 ratio in water); total (LECO combustion), dithionite-citrate and oxalate-extractable Fe and Al; and water-extractable PO$_4^{3-}$ and SO$_4^{2-}$ (1:20 soil solution ratio; shaking for 1 h). Iron and Al in the extractant solutions were analyzed by atomic absorption, PO$_4^{3-}$ in the NH$_4$F/HCl extractant solution was analyzed by Technicon Autoanalyzer, SO$_4^{2-}$ in the Na$_2$PO$_4$ extract solution was analyzed by the Ba chloranilic procedure of Bertolacini and Barney (1957), and PO$_4^{3-}$ and SO$_4^{2-}$ in the water extracts were analyzed by Technicon Autoanalyzer. Detection limits were <0.1 mmol kg$^{-1}$ for Ca, <0.02 mmol kg$^{-1}$ for chloride-dithionite Fe and Al, <0.2 and <0.7 mmol kg$^{-1}$ for oxalate-extractable Fe and Al (respectively), <0.01 mmol kg$^{-1}$ for NH$_4$F/HCl extractable PO$_4^{3-}$, <0.05 mmol kg$^{-1}$ for Na$_2$PO$_4$ extractable SO$_4^{2-}$, and <0.01 mmol kg$^{-1}$ for water-extractable PO$_4^{3-}$ and SO$_4^{2-}$.

Tension lysimeters were installed in the A (8 cm) and B horizons (50-80 cm) of each plot. Solutions were collected continuously at 10-kPa tension and sampled on approximately a 30-d basis (more frequently during rainy periods and less frequently during droughty periods).

After 120 d of monitoring the lysimeter waters, one of the four plots was treated with 0.5 mol(-) m$^{-2}$ of Na$_2$PO$_4$, Na$_2$SO$_4$, NaCl, and NaNO$_3$ salts as a test of Hypotheses I and II.

Water samples were analyzed at each institution separately (Analytical Chemistry Division at ORNL and the College of Forest Resources at the Univ. of Washington, Seattle). Cross comparisons between laboratories were made and results were comparable. All waters were analyzed for pH, conductivity, Ca$^{2+}$, Mg$^{2+}$, K$^+$, and Na$^+$ (the latter four by atomic absorption); for NH$_4^+$, NO$_3^-$, PO$_4^{3-}$, Cl$^-$, and SO$_4^{2-}$ (by Technicon Autoanalyzer); and for alkalinity by titration. Detection limits were <0.005 mmol L$^{-1}$ in all cases. Further checks of analyses were made by charge balance between cations and anions and by comparing calculated with measured conductivity (Golterman and Clymo, 1969).

**Laboratory Studies**

As additional tests of Hypotheses I and II, anion adsorption isotherms were determined at ORNL on the soils from the four sites before treatment (one each per horizon and treatment plot, giving four replicates per horizon per site). Successive 50-mL aliquots of 0.5, 1.0, 2.5, and 5.0 mmol(-) L$^{-1}$ of Cl$^-$, NO$_3^-$, H$_2$PO$_4^-$ as Na$^+$ salts, and SO$_4^{2-}$ as Na$^+$.
and Ca\(^{2+}\), salts (using separate soil samples for each salt) were applied to 5-g air-dried, sieved (<2 mm) soil in a mechanical vacuum extractor (Conert Engineering, Inc.) at a 1:1 extraction time setting. Each column (2.5-cm diam by 13.2-cm length) was prepacked with 1 g of ashless filter pulp, and two columns were left without soils (as blanks). Adsorption or desorption of anions was calculated by disappearance or appearance of anions in the eluent solution (after accounting for interstitial water and blank adsorption-desorption) as described by Johnson and Henderson (1979). Calculated soil anion contents during adsorption studies included pretreatment soil anion previously determined as described above. Anion adsorption studies originally done with Na\(^+\) salts gave extremely variable results except in the case of phosphate. Sulfate adsorption was done again using Ca\(^{2+}\) salts with much more satisfactory results (i.e., less variation and more differentiation among soils). No Cl\(^{-}\) or NO\(_3\) adsorption was noted in any soil, and thus only phosphate and SO\(_4\)\(^{2-}\) adsorption results are shown here.

A final test of Hypotheses I and II was made by setting up a column study to duplicate field Na\(^+\) salt applications. Triplicate columns of the type described above were filled with 30-g samples of air-dried, sieved A and B horizon soils sampled before treatment from each salt-treated plot. The A horizon columns were pretreated with approximately 250 μmol(-) each of Cl\(^{-}\), NO\(_3\), H\(_2\)PO\(_4\), and SO\(_4\) as Na\(^+\) salts. (Actual input values as determined by outputs from columns without soil, varied from 235 μmol(-) to 280 μmol(-) per column). These columns were then leached with four 150 mL aliquots of distilled water, of which 75 mL was kept for analysis and 75 mL was washed through B horizon columns. All waters were analyzed for pH, HCO\(_3\), H\(_2\)PO\(_4\), SO\(_4\), Cl\(^{-}\), NO\(_3\), and conductivity.

A second column study was set up to test Hypothesis III using soils from the Fullerton and Douglas-fir control plots. The A and B horizon columns were set up as described above. Triplicate A horizon columns were leached with 4 150-mL aliquots of H\(_2\)O, HCl, NaCl, and CaCl\(_2\), the latter at concentrations of 1.0 mmol(-) L\(^{-1}\). The B-horizon columns were leached with 75-mL of the 150-mL A-horizon leachates. All waters were analyzed for pH, HCO\(_3\), SO\(_4\), NO\(_3\), H\(_2\)PO\(_4\), Cl\(^{-}\), conductivity and Al\(^{3+}\) (the latter by atomic absorption).

Statistical analyses (standard deviation calculations, Duncan's multiple range test) were performed using SAS (SAS Institute, 1982).

**RESULTS AND DISCUSSION**

With one exception (dithionite–citrate-extractable Fe [Fe\(_d\)] in the Fullerton Bt horizon), the Washington (Alderwood) soils were as high or higher in Fe and Al hydrous oxides than the Tennessee (Fullerton and Tarklin) soils (Table 1). This was especially so for oxalate-extractable Al (Al\(_e\)) where the Washington soils had 4 to 10 times greater contents than the Tennessee soils (Table 1). The Washington soils also had approximately 1.5 to 4 times greater oxalate-extractable Fe (Fe\(_e\)) contents and approximately two times greater surface soil dithionite-extractable Al (Al\(_d\)) contents than the Tennessee soils (Table 1).

The ratio Fe\(_e\)/Fe\(_d\) gives an index of the crystallinity of Fe hydrous oxides, which in turn provides an index of the degree of aging (Blume and Schwertmann, 1966). According to this index, Fe hydrous oxides in the Washington soils are only slightly less crystalline than those in the Tennessee soils (Table 1). The meaning of the Al\(_e)/Al\(_d\) ratio in terms of Al crystallinity is not well-defined (Blume and Schwertmann, 1966; Mc-Keague and Day, 1966), but it is worth noting that these ratios are considerably higher for the Washington than for the Tennessee soils (Table 1).

McKeague and Day (1966) note that the difference between Fe\(_e\) and Fe\(_d\), or Fe\(_e\) = Fe\(_d\) = Fe\(_e\) provided a good chemical index of crystalline Fe hydrous oxide content. Again, the meaning of Al\(_e\) = Al\(_d\) and Al\(_d\) is less clear. In any event, the Washington soils have higher Fe\(_e\) and Al\(_e\) contents in surface horizons but lower Al\(_e\) contents in subsurface horizons than the Tennessee soils (Table 1). For subsurface horizon Fe\(_e\), the Fullerton soil was by far the highest and the other soils were about equal.

The phosphate and sulfate adsorption isotherms were very similar to one another in terms of relative curve positions and shapes for the various soils (Fig. 1). For both anions, the A horizon adsorption capacities were (in decreasing order) Red alder > Douglas-fir > Fullerton = Tarklin. In the B horizons, the capacities were Red alder > Douglas-fir ≈ Fullerton > Tarklin. These patterns were mostly closely correlated with Al\(_d\) and, to some extent, with Al\(_e\) but not particularly well with Fe\(_e\), Fe\(_d\), Al\(_e\), or Fe\(_e\) (Table 1).

Johnson and Todd (1983) found that Fe\(_e\) was most closely correlated with sulfate adsorption among a variety of forest soils. On the other hand, Parfitt and Smart (1978), in a more rigorous, mechanistic study, found that more highly crystalline Fe hydrous oxides (such as goethite and hematite) have lower sulfate adsorption capacities than less crystalline Fe hydrous oxides because of fewer singly-coordinated surface hydroxyl ions in the former. The results of the current study tend to support the view that highly crystalline Fe hydrous oxides are not particularly efficient at either sulfate or phosphate adsorption (in comparison, at least, to seemingly less crystalline Al hydrous oxides). This implies that Hypothesis I is false and leads to the alternative hypothesis that the most highly-weathered soils, with the most crystalline Fe and Al hydrous oxides, will have lower anion adsorption capacities than less weathered soils with lower Fe and Al hydrous oxide crystallinity.

The question remains as to the effect of organic matter. Some studies have shown that organic matter in-

† Calculated water flux = 280 cm (Knutsen, 1965).
‡ Calculated water flux = 130 cm (Luxmore, 1983).
most phosphate, followed by the Douglas-fir, Fullerton, and Tarklin soils, respectively (Fig. 2 and Table 2). Phosphate adsorption apparently caused net desorption of native soil sulfate from A horizons of salt-treated soils, both in laboratory column and field studies (Fig. 2 and Table 2). There also was a net sulfate release from all but the red alder B horizon in the column studies, apparently a result of phosphate inputs from A horizon leachates (Fig. 2). In the red alder soil, B horizon columns showed a net retention of sulfate, presumably due to the lower phosphate inputs from A horizon leachates and the greater sulfate adsorption capacity of this soil.

Both of the Washington Inceptisols retained applied sulfate in field studies, whereas neither of the Tennessee Ultisols did (Fig. 3). After 2 yr (and approximately 280 cm of leaching), the red alder soil showed no net sulfate export (in excess of control plots) and the Douglas-fir soil showed a net export (in excess of control) of only 0.24 mmol(-) m(-2), or roughly 50% of applied sulfate (Table 2). On the other hand, the Fullerton and Tarklin soils showed net exports (in excess of control) of 0.65 and 0.84 mmol(-) m(-2) (130 and 168% of applied sulfate) after only 130 cm of leaching (Table 2). (Annual leaching rates were lower in the Tennessee soils due primarily to higher evapotranspiration.)

Flux calculations in field lysimeter plots are subject to many uncertainties (one of which is the appropriate water flux to apply), and thus the apparent release of native soil sulfate from the Tennessee soils may have been an artifact. This was not the case in the laboratory studies, however, where fluxes were accurately measured and clearly showed net sulfate release due to phosphate adsorption. In any case, the patterns of sulfate retention in B horizons in the field studies followed those of the adsorption isotherms, namely red alder > Douglas-fir > Fullerton > Tarklin.

Hypothesis II was supported by the results of the laboratory and field studies. No net NO3 retention was observed in any of the soils in the column studies (Fig. 2). The Na+ salt application studies did not provide adequate tests of Hypothesis III; however, because of the confounding effects of phosphate and sulfate adsorption on soil solution pH. Thus, Hypothesis III was tested in a series of column studies on the Douglas-fir and Fullerton soils involving chloride applications as NaCl, CaCl2, and HCl.

Chloride was mobile in all soils in both laboratory and field studies (Fig. 2 and Table 3), confirming its chemical and biological inertness. The Na+ salt application studies did not provide adequate tests of Hypothesis III, however, because of the confounding effects of phosphate and sulfate adsorption on soil.

![Graph showing pH, Al^3+, HCO_3^-, and SO_4^2- concentrations in leachates from A horizon soil columns treated with H_2O, NaCl, CaCl_2, and HCl at 1.0 mmol(-) L(-1).](image)
The chloride application studies supported Hypothesis III in that inputs of chloride, as salt or acid, caused lowered pH, HCO$_3^-$, and SO$_4^{2-}$ concentrations in leachates as compared to water applications (Fig. 3 and 4). The effects depended on the cation associated with chloride input, with the degree of effect being HCl > CaCl$_2$ > NaCl > H$_2$O. The HCl and, to a lesser extent, the CaCl$_2$ treatments also stimulated Al leaching (most markedly in the more acid Fullerton soil and more markedly in A horizons than in B horizons for both soils). No effects of chloride input on NO$_3^-$ were noted, and no significant net retention or release of chloride was noted except for that accounted for from control (H$_2$O-treated) columns. Phosphate was assumed to be a minor contributor to total anion concentration and, therefore, was not determined in this particular study.

Treatments with chloride caused reductions in the net export of bicarbonate and sulfate with the level of reduction being HCl > CaCl$_2$ > NaCl in most cases (Table 3). No net change in chloride export could be detected, due in part to the large background chloride (and background Cl$^-$ variability) in chloride-treated columns. Nitrate export was low (<1 mmol/column) and not affected by treatment.

**SUMMARY AND CONCLUSIONS**

Laboratory and field studies tested hypotheses concerning anion movement and retention in forest soils. Two Ultisols (Fullerton and Tarklin series), both with deciduous forest cover in eastern Tennessee, and two Inceptisols (both Alderwood series), one with Douglas-fir and one with red alder forest cover in western Washington were studied. We hypothesized that sulfate and phosphate retention in the four forest soils would be related to Fe and Al oxide content, which in turn would be related to soil parent material and degree of weathering. This hypothesis was not supported by results of soil Fe and Al hydrous oxide analyses, adsorption isotherm determinations, or applications of sulfate and phosphate as Na$^+$ salts to laboratory columns and field plots. The Washington Inceptisols (especially the red alder site) adsorbed more sulfate and phosphate than the Tennessee Ultisols. Apparently, this was due to greater amorphous hydrous Fe and Al oxide contents in the former. Hydrous Fe and Al oxides in the Tennessee subsoils appeared to be more crystalline. Consequently, they were less able to adsorb sulfate and phosphate.

A second hypothesis that NO$_3^-$ retention was governed by biological processes was supported by laboratory and field results of NaN$_2$O$_3$ application. No soil retained NO$_3^-$ in laboratory studies where forest floor and trees were excluded, but most of the applied NO$_3^-$ was retained in B horizons of all but the N-rich red alder soil, suggesting tree uptake as a major cause of NO$_3^-$ immobilization in the ecosystem.

The third hypothesis stated that manipulations causing solution pH to rise would increase leaching of bicarbonate and adsorbed anions (and vice versa) and that inputs of mobile anions like chloride would lower solution pH and cause net anion retention. This hypothesis was supported by applications of HCl, NaCl, and CaCl$_2$ (compared to H$_2$O only) to soil columns. Chloride applications lowered solution pH and reduced the leaching bicarbonate and sulfate with the order of effectiveness being HCl > CaCl$_2$ > NaCl for a given chloride concentration.

Physical and Chemical Soil Properties of Three Big Sagebrush Subspecies

SHERMAN R. SWANSON, GERALD H. SIMONSON, AND JOHN C. BUCKHOUSE

ABSTRACT

The three subspecies of Artemisia tridentata Nutt. typically occupy qualitatively different sites. Wyoming big sagebrush, A. t. ssp. wyomingensis, commonly grows in Aridisol; mountain big sagebrush, A. t. ssp. vasyana, commonly lives in Mollisol at a higher average elevation; and basin big sagebrush, A. t. ssp. tridentata, occurs in deep soils of either order. This study evaluated some physical and chemical characteristics of surface and subsurface soil horizons of soils occupied by each subspecies in four widely spaced Oregon locations. Most soil chemical characteristics showed no significant differences between subspecies. Interaction between location and subspecies often indicated that analysis should proceed at each individual location. The Frenchglen location had the greatest elevational differences between sites and also had most statistically significant soil differences between subspecies. Many of the measured characteristics are interrelated and differences in them probably are influenced by elevation-related variation in climate. Surface horizons of Frenchglen, A. t. ssp. vasyana sites had lower pH, base saturation, and exchangeable Na+ and higher organic matter, cation exchange capacity, and water retention at ~1.50 MPa than surface horizons of A. t. ssp. wyomingensis sites. Fewer surface soil characteristics of A. t. ssp. tridentata sites were significantly different. In deeper soil horizons at Frenchglen, A. t. ssp. vasyana sites had lower pH and base saturation than A. t. ssp. tridentata sites.

Additional Index Words: Artemisia tridentata, organic matter, cation exchange capacity, base saturation, soil depth, soil texture, soil-water retention.

Vegetation and soil characteristics are interdependent integrators of environmental factors. Understanding the indicator value of vegetation can be useful to land managers, especially where soil and vegetation are correlated over broad areas of the
