Abstract. A quantitative model-observation comparison of multiple polar cap arcs has been conducted by using a time-dependent theoretical model of polar cap arcs. In particular, the electrodynamic features of multiple polar cap arcs with various spacings are simulated and the results are compared with the images obtained from the All-Sky Intensified Photometer at Qaanaaq. The results show that the observed and simulated arcs are quite similar, both spatially and temporally. The results support the theory proposed by *Zhu et al.* [1993a, 1994b] that the structure of polar cap arcs is mainly determined by the magnetosphere-ionosphere (M-I) coupling processes and that the spacing of multiple polar cap arcs is closely related to the hardness of the primary magnetospheric precipitation. It is found that for the multiple polar cap arcs with both narrow and wide spacings, the associated field-aligned currents are mainly closed by Pedersen currents. It is also found that a hard precipitation can lead to a highly structured secondary arc because of the nonlinear M-I coupling processes.

1. Introduction

Polar cap arcs are the auroral arcs seen at very high geomagnetic latitudes ($> 80^\circ$) that extend from 100 km up to the size of the whole polar cap and that are aligned parallel to the Sun-Earth direction [Davis, 1960; Nielson *et al.*, 1990]. The arcs are mainly observed during northward interplanetary magnetic field (IMF) and quiet magnetic conditions. Some of the arcs are very bright and luminous and cross the entire polar cap from the dayside to the nightside of the auroral oval to form a pattern that resembles the Greek letter "theta" [Frank *et al.*, 1986; Nielsen *et al.*, 1990]. Other arcs are confined to the polar cap and are relatively weak, and these tend to be either in the evening or morning sectors of the polar cap [Weber and Buchau, 1981; Carlson *et al.*, 1984; Rich *et al.*, 1990]. Some observations suggest that the Sun-aligned arcs at high latitudes are in regions of open field lines because polar rain electrons are sometime observed adjacent to and outside of the arcs [Hardy *et al.*, 1982]. However, in other observations, the precipitating electrons have the characteristics of the plasma sheet or plasma sheet boundary layer, suggesting that the arcs are on closed field lines [Peterson and Shelley, 1984; Obara *et al.*, 1988]. It has been confirmed by many observations that the arcs are associated with upward field-aligned currents carried by energetic precipitating electrons, with the energy range extending from a few hundred eV to a few keV [Hardy *et al.*, 1982; Valladares and Carlson, 1991].

More recently, a series of campaigns conducted under the auspices of the CEDAR High Latitude Plasma Structure (HLPS) Working Group have accumulated a wealth of new information on polar cap arcs and have extended our observations from the

large-scale, steady state features to the more dynamical, mesoscale features of polar cap arcs. The new observations have provided information on, for example, the dawn-dusk motion and the multiple fine structure of polar cap arcs [Valladares *et al.*, 1994], the sudden rotation of the adjacent convection prior to the breakup of polar cap arcs [Berg, 1992], and the field-aligned depletions of *F* region plasma [Doe *et al.*, 1992].

Compared to the observations, theoretical studies of polar cap arcs, especially quantitative studies, are still in an early stage. On the basis of S3-2 data, Burke *et al.* [1982] proposed a model for polar cap arcs that occur on open field lines. By introducing the concept of a multiple bifurcation of magnetic field lines, Kan and Burke [1985] constructed a model of polar cap arcs and proposed that theta aurora can occur on closed field lines and that the less intense polar cap arcs can occur either on closed or open field lines. More recently, Chiu [1989] formulated a model in which polar cap arcs are assumed to be on open field lines, and he showed that the formation of polar cap arcs is due to the current response to a mesoscale velocity shear structure in the ionosphere. Because these theoretical models are either qualitative, semiquantitative, or steady state models, they cannot be used to study the dynamical features associated with both the temporal evolution and the fine spatial structure of polar cap arcs. Also, these models cannot be used in a detailed quantitative comparison with observations, which is essential for furthering our understanding of the dynamics of polar cap arcs.

Recently, we have conducted a series of polar cap arc studies using a time-dependent magnetosphere-ionosphere (M-I) coupling model [Zhu *et al.*, 1993a, b; Sojka *et al.*, 1994; Zhu *et al.*, 1994a, b]. These studies have provided satisfactory "theoretical" explanations for a number of important issues concerning polar cap arcs, which include the active role of the ionosphere for the formation of the arcs, the appearance of multiple arcs, and the physical parameters determining the spacing of multiple arcs.

In this paper, we present the results obtained in a detailed quantitative comparison of the M-I coupling model with

¹Institute for Space Research, Boston College, Newton, Massachusetts.

were taken and about 30% of them have polar cap arcs. Among the images having polar cap arcs, at least 80% of them show the multiple arc structures. The development of multiple polar cap arcs is quite dynamical. In about 85% cases of multiple polar cap arcs, the arcs with a multiple structure did not appear simultaneously. It is quite common that new arcs develop near the arc that appear in a early time to form multiple structures. The locations of individual arcs are not spatially stable, and they typically move in a dawn-dusk direction with a speed that ranges from tens of meters per second to several hundred meters per second. The typical spacing of the structured arcs can range from tens of kilometers to a few hundred kilometers. This paper is not to touch the details of the above statistical features of multiple polar cap arcs. Instead, we choose two typical cases of multiple arcs based on the above statistical results and perform model-observation comparison study to test the model predictions and reveal more dynamical features of the arcs.

Figure 1 shows an image taken by the all-sky camera at Qaanaaq at 0826 UT, November 12, 1990. Clearly, the polar cap arcs are structured and the edge-to-edge spacing (the width of the dark region between two arcs) is found to be about 40 km. These polar cap arcs are not the transpolar arcs, instead, they are localized and confined to the morning sector of the polar cap.

3. Theoretical Model

The modeling of multiple polar cap arcs was conducted by using the time-dependent M-I coupling model developed by Zhu *et al.* [1993a]. The mathematical formulation of the model will not be discussed in this paper and the interested readers are referred to the Zhu *et al.* [1993a] paper. A key feature of this M-I coupling model of polar cap arcs is that the arcs are not treated as phenomena merely controlled by the magnetosphere, with the ionosphere only acting as a passive load. Instead, the polar cap arcs are treated as the processes that are coherently determined by the dynamics in both the ionosphere and magnetosphere.

Initially, a magnetospheric shear flow carried by Alfvén waves propagates towards the ionosphere. The significance of the assumed initial magnetospheric shear flow in the model has been discussed by Zhu *et al.* [1993a] and is not repeated here. The downward propagating Alfvén waves are partially reflected from the ionosphere and then bounce back and forth between the ionosphere and magnetosphere. The nature of the wave reflections depends on both the conditions in the ionosphere and magnetosphere. The propagating Alfvén waves carry both upward and downward field-aligned currents. The precipitating electrons associated with upward field-aligned currents enhance the conductivity in the ionosphere. The modified ionospheric conductivity launches secondary Alfvén waves towards the magnetosphere. The upward propagating Alfvén waves, which consist of the reflected waves and the secondary Alfvén waves launched by the temporal change of the ionospheric conductivity, carry the ionospheric information back to the magnetosphere, thus reflecting the active ionospheric role in the dynamics of the M-I coupling process. The whole process is transient, during which all physical quantities in the ionosphere change self-consistently in time, and subsequently, polar cap arcs develop. Because of the finite conductivity in the ionosphere, the temporal variation of the Alfvén waves in the coupled M-I

system diminishes with time, and the M-I system, as well as the development of polar cap arcs, approach an asymptotic steady state after several bounce periods.

One important issue that need to be addressed here is the treatment of the relationship between the Alfvén waves and the conductivity enhancement caused by precipitations. Due to the great variation of the Alfvén speed along the magnetic field lines, the resonance between the precipitating particles and the Alfvén waves may not be able to sustain all the time. To avoid the complicated wave-particle interaction component in the model, we use the following simplified approach to tackle the issue. On the basis of MHD theory, enhanced E field associated with Alfvén waves leads to an enhanced field-aligned current. By assuming a linear relationship [Fridman and Lemair, 1980], we connect the upward field-aligned current and the field-aligned potential drop. The increasing potential drop along magnetic field lines causes the energization of the current carriers (we assume mainly electrons). By using continuity equation, we treat the conductivity enhancement caused by the energized precipitating electrons. In the reality, the picture for the connection between the Alfvén waves and the resulted conductivity enhancement could be much more complicated.

The ionosphere is treated as a two-dimensional slab with an integrated conductivity. The X axis measures the noon-midnight dimension and points to the dayside, and the Y axis measures the dawn-dusk dimension and points to the duskside. The magnetosphere is a two-dimensional pseudoplane that is used as a boundary for the reflection of Alfvén waves. The magnetosphere and ionosphere are connected by magnetic field lines which are assumed to be perpendicular to the ionosphere. The communication between the magnetosphere and ionosphere is characterized by the bouncing of Alfvén waves between the two regions, and both the upward and downward field-aligned currents are associated with the propagating Alfvén waves. Initially, the large-scale ionospheric convection and conductivity are specified. These large-scale patterns are consistent with the overall solar, geomagnetic, and IMF conditions.

Interesting theoretical results concerning the electrodynamics of multiple polar cap arcs have recently been obtained with the M-I coupling model. With this model, Zhu *et al.* [1993a] showed that multiple polar cap arcs might not be due to multiple structures in the magnetospheric source region. Instead, they can be internally generated in the M-I system as a result of the self-consistent coupling of the magnetosphere and ionosphere. Sojka *et al.* [1994] found that the appearance of multiple polar cap arcs has a strong dependence on the magnitude of the large-scale ionospheric background convection (E). With the same initial magnetospheric driver, they found that the number of the arcs increased with an increase in the strength of the background convection, while the spacing between the arcs remained constant. This dependence is "not" a linear effect in which the polar cap arcs simply scale with the magnitude of the background convection. The degree of striation, or multiple character, of the arcs increases rapidly from a single arc at $E < 20$ mV/m to 5 arcs at 30 mV/m. These results further indicate that the ionosphere plays an active role in the formation of multiple polar cap arcs and that the ionosphere dynamically responds to the magnetospheric driver. Expanding on the Sojka *et al.* [1994] results, Zhu *et al.* [1994b] reached a qualitative theoretical conclusion about the appearance and spacing of multiple polar cap arcs. They predicted that

Figure 2. A schematic diagram showing the location of the ionospheric simulation domain in the polar cap. A magnetic latitude-magnetic local time (MLT) coordinate is used.

multiple polar cap arcs are more likely to occur when the large-scale ionospheric convection field is larger than 20 mV/m and the background ionospheric Hall conductance is in the range of from 0.5 to 2 mho. When the large-scale convection is weak and the ionospheric conductance is high, a single arc is more likely to be seen in the polar cap. With a variable conductance ratio, it was found by Zhu *et al.* [1994b] that the spacing of multiple polar cap arcs is mainly determined by the hardness of the primary magnetospheric precipitation. A harder precipitation causes a wider spacing between individual arcs and vice versa. The edge-to-edge spacing between arcs varies from about 20 km to about 60 km when the ratio of the enhanced Hall and Pedersen conductances changes from 1 to 2.

The above quantitative theoretical predictions concerning multiple polar cap arcs can be tested with the Qaanaaq data. By using model inputs that are consistent with the conditions when the observed multiple polar cap arcs occurred, we can compare the time-dependent electrodynamic features of both the simulated and observed arcs. If the corresponding spatial and temporal scales are largely consistent, that would confirm the theoretical predictions made by the M-I coupling model to zero-order. Also, the modeling results would provide a much more detailed picture of the electrodynamic features of multiple polar cap arcs than the observations. The model yields information about the conductivity enhancement, the Joule heating, the connection between field-aligned currents and horizontal currents, the cross-flow associated with multiple polar cap

arcs, etc. Such information would improve our understanding of the underlying physics of multiple polar cap arcs.

4. Model-Observation Studies

Case 1: November 12, 1990

The polar cap arcs observed on November 12, 1990, occurred in the morning sector of the dark polar cap. The time period we are interested in is from 0822 to 0828 UT, during which the arcs went through the stages from breaking up to a quasi-steady state. During this time period, the IMF B_z was positive (~ 1.5 nT) and B_y was negative (~ -1.5 nT). Before this period, the IMF B_z component had been positive for almost 24 hours, and after the period under study the IMF B_z remained positive for another 24 hours. The K_p index was 1- for almost 9 hours. This is a typical condition for the occurrence of polar cap arcs.

The location of the ionospheric simulation domain in the polar cap for case 1 is shown in Figure 2. The simulation domain is 1500 km long in the X (midnight-noon) direction and 1000 km wide in the Y (dawn-dusk) direction. The grid size is 30 km in the X direction, and 10 km in the Y direction. It should be noted that Figure 2 is just a schematic diagram and is not precisely scaled. With the M-I coupling model, we need to specify some initial conditions, which include the large-scale background convection and background conductance patterns before the breakup of the polar cap arcs and the small-scale shear flow associated with the arcs. Unfortunately, for both observational periods in this study, there were either no DMSP data or the pass of DMSP was far away from the field of view of the all-sky camera. Therefore the DMSP satellite was not able to provide information on either the large-scale convection pattern or the small-scale shear flow associated with the arcs for the modelings. Hence we had to use

Figure 3. Potential distribution in the dawn-dusk cross section associated with the initial magnetospheric shear flow (solid) and the corresponding electric field distribution (dashed).

Figure 4. (left) A sequence of the images showing polar cap arcs starting at 0822 UT, November 12, 1990, with a 2-min interval and (right) the snapshots of the evolution of the field-aligned current distribution from the modeling. The dashed lines indicate upward field-aligned currents. The ionospheric dimension of the images in the left column is about 1430 km in noon-midnight (X) direction and about 1165 km in dawn-dusk (Y) direction.

Figure 5. The distributions of the (top) enhanced Hall conductance and (bottom) Joule heating rate near the asymptotic steady state (0826 UT). No neutral wind effect is included in the calculation of the Joule heating rate.

statistical large-scale convection patterns for the IMF and geomagnetic conditions similar to those when the polar cap arcs occurred. On the basis of the *Heppner and Maynard* [1987] convection model, the large-scale background convection in the region where the arcs occurred for case 1 is basically uniform and antisunward. The background ionospheric conductance for the modelings was obtained from the conductivity model developed by *Rasmussen et al.* [1988]

using the appropriate geomagnetic, solar, and seasonal conditions.

The M-I coupling model also needs the initial small-scale shear flow originated in the magnetosphere. Since *Zhu et al.* [1994b] found that the appearance and spacing of "multiple" polar cap arcs are not determined by the spatial scale of the initial magnetospheric shear flow and they are determined by the M-I coupling processes, we used the same shear flow

profiles for both of the cases we studied. The initial small-scale shear flow was assumed to be carried by a downward propagating Alfvén wave. It extended uniformly along the Sun-aligned direction (X direction) and had a "single" precipitation channel. The cross-section profiles of the electric field associated with the assumed initial small-scale shear flow (dashed line) and the corresponding electric potential (solid line) are shown in Figure 3.

It should be noted again that a guideline for our simulations is the theoretical results of Zhu *et al.* [1994b]. They found that the observed multiple polar cap arcs may not be due to multiple structures in the magnetosphere, but instead may primarily be determined by the coupled magnetosphere-ionosphere system in which the ionosphere plays an active role. The spacing of multiple polar cap arcs is mainly determined by the hardness of the primary magnetospheric precipitation. A harder precipitation causes a wider spacing between individual arcs and vice versa. Accordingly, for case 1, in which the arcs have a narrow spacing, we assumed that the ratio between Hall and Pedersen conductances is 1.4, which reflects a relatively soft precipitation.

The simulation for case 1 started at 0818 UT, which is the time when the assumed downward propagating Alfvén wave hit the ionosphere. Figure 4 shows snapshots of the evolution of the field-aligned current distribution from the modeling (right column) and the corresponding time sequence of polar cap arc images (left column). From the images, starting at 0822 UT with a 2-min interval, we can see that the polar cap arcs started to appear at 0822 UT and took about 6 min to reach a steady state. The arcs were structured with an edge-to-edge spacing

(dark region between two arcs) of about 40 km. The arcs were aligned mainly in the noon-midnight direction. The first plot of the modeled field-aligned currents is for 0822 UT, which is 4 min after the initial magnetospheric shear flow reaches the ionosphere. The successive plots are also at 2-min intervals. The dashed lines represent the upward field-aligned currents. Comparing the left and right columns, it is apparent that both the spatial and temporal features of the model predictions and measurements are quite similar except the intensity of the poleward arc at 0824 UT. These similarities indicate that our adopted initial conditions for the modeling are largely reasonable and that the M-I coupling model describes the appropriate physics associated with multiple polar cap arcs.

Figure 5 shows the distributions of the enhanced Hall conductance (top panel) and the Joule heating rate (bottom panel) at the asymptotic steady state (0826 UT). It can be seen that the Hall conductance is enhanced from about 0.5 mho (background conductance) to a peak conductance of 8 mho and that the enhanced conductance is structured. The Joule heating rate is also substantially increased and structured. It should be noted that there is no neutral wind effect in the calculation of Joule heating rate.

Figure 6 shows the cross-section profiles of the modeled total field-aligned current, the Hall and Pedersen components of the field-aligned currents, and the cross-flow associated with the polar cap arcs at 0826 UT, as obtained from the modelings. A negative value in the field-aligned current plots means upward current. These cross-section profiles clearly show the multiple structure of the polar cap arcs. Comparing the first three plots in Figure 5, we can see that the field-aligned currents associated with multiple polar cap arcs are mainly closed by the Pedersen currents, and only a small part of the field-aligned currents is closed by the Hall currents. The Hall current contribution to the field-aligned currents is due to the small-scale conductivity gradient caused by the arc precipitation. It should be noted that if the ionosphere is in a steady state and the conductivity is uniform, there is no Hall current component of field-aligned currents. However, if the ionospheric system is temporally varying or the conductivity is nonuniform, the Hall current can make contribution to the field-aligned current. In principle, the closure of the ionosphere-originated field-aligned currents, which could include both Pedersen and Hall components, at the magnetosphere is achieved through the adjustment of magnetic field configuration in the magnetosphere. However, the detailed picture is still not clear and the mechanism for the current closure at the magnetosphere has not been self-consistently treated in our model. The bottom panel shows that a cross flow exists in association with the multiple polar cap arcs, but the magnitude of the cross flow is small. It should be noted that this cross-flow results from the M-I coupling processes associated with the multiple arcs, since the initial magnetospheric shear flow is symmetric and does not contain a cross flow.

Case 2: December 11, 1990

The polar cap arcs observed on December 11, 1990, occurred in the evening sector of the dark polar cap. The time period we are interested in is from 2112 to 2118 UT. The IMF turned northward at about 1800 UT and remained northward until 0030 UT of the next day. During the period we are interested in, the B_z was ~ 5 nT and B_y was ~ -1.5 nT, and Kp

Figure 6. The cross-section profiles of the total field-aligned current, the Hall and Pedersen components of the field-aligned currents, and the cross flow associated with the polar cap arcs at 0826 UT from the modelings. The negative values of field-aligned current mean the upward field-aligned currents.

Figure 8. The distributions of the (top) enhanced Hall conductance and (bottom) Joule heating rate near the asymptotic steady state (2118 UT). No neutral wind effect is included in the calculation of the Joule heating rate.

Figure 7. (left) A sequence of images showing polar cap arcs starting at 2112 UT, December 11, 1990, with a 2-min interval and (right) the snapshots of the evolution of the field-aligned current distribution from the modeling.

was 1. This is also a typical condition for the occurrence of polar cap arcs. The location of the ionospheric simulation domain in the polar cap for case 2 is schematically shown in Figure 1.

For this case, the DMSP-F8 pass was about 1000 km away from the edge of the field of view of the all-sky camera. Therefore we again had to depend on statistical convection models for information about the large-scale background convection pattern. The *Heppner and Maynard* [1987] convection model shows that under the above specific IMF and geomagnetic conditions, the convection in the region where the multiple arcs in case 2 occurred is also basically uniform and antisunward. Then, by using the same magnetospheric shear flow and background ionospheric conductance as for case 1, we conducted the modeling for case 2. The ratio of the Hall and Pedersen conductances for case 2 is 1.9, which is different from that in case 1 and reflects a relatively harder precipitation.

The simulation for case 2 started at 2108 UT, which is the time when the assumed downward propagating Alfvén wave hit the ionosphere. Figure 7 shows snapshots of the evolution of the field-aligned current distribution from the modeling (right column) and the sequence of polar cap arc images (left column). The images start at 2112 UT with a 2-min interval. The arc pattern consists of two arcs with an edge-to-edge spacing of about 90 km, which is much wider than that in case 1. The arcs are again aligned mainly in the noon-midnight direction. It may be noticed that there is a significant bending associated with the equatorward arc at 2118 UT. This bending is due to the instrument effect which occurs when the altitude of the arc varies significantly along the arc and the arc is far away from the center of the field of view. The first plot of the modeled field-aligned currents is for 2112 UT, which is 4 min after the initial magnetospheric shear flow reaches the ionosphere. The successive plots are also at 2-min intervals. Again, a comparison of the left and right columns indicates that the two are quite similar, both spatially and temporally.

Special attention needs to be paid to the second arc. *Zhu et al.* [1993a] suggested that the nature of the primary and secondary arcs could be quite different. The primary arc is directly related to the magnetospheric driver. The appearance of the secondary arc and the spacing between the primary and secondary arcs are largely determined by the M-I coupling processes. Here, as a nonlinear response to a harder magnetospheric precipitation from the coupled M-I system, there is a wider spacing between the primary and secondary arcs. Also, the secondary arc shows fine structure feature. The feature of fine structure in the secondary arc from the simulation for the situation of hard precipitation is quite similar to that of the secondary arc in the images. This correspondence is a surprising finding. Further theoretical and modeling are needed to explore the underlying physics of this new feature.

Figure 8 shows the distributions of the enhanced Hall conductance (top panel) and the Joule heating rate (bottom panel) near the asymptotic steady state (2118 UT). It can be seen that the Joule heating associated with the secondary arc is distributed. Figure 9 shows the cross-section profiles of the total field-aligned current, the Hall and Pedersen components of the field-aligned currents, and the cross-flow of the polar cap arcs at 2118 UT, as predicted by the modelings. From Figure 6, we can see that in the case of the arcs with a wide spacing, the field-aligned currents associated are also mainly

Figure 9. The cross-section profiles of the total field-aligned current, the Hall and Pedersen components of the field-aligned currents, and the cross flow associated with the polar cap arcs at 2118 UT from the modelings. The negative values of field-aligned current mean the upward field-aligned currents.

closed by Pedersen currents. In addition to the two distinct arcs, fine structure is clearly evident in the secondary arc. The bottom panel shows that there also exists a cross flow for the multiple polar cap arcs with a wide spacing, but the cross flow is considerably more distributed than that for the arcs with a narrow spacing, case 1.

5. Discussion and Conclusion

For a first time, a quantitative model-observation comparison of multiple polar cap arcs has been conducted by using a time-dependent theoretical model of polar cap arcs and the initial results are encouraging. The arcs observed with the all-sky camera at Qaanaaq and the simulated ones are quite similar, both spatially and temporally. This direct comparison study of both temporal and spatial features of polar cap arcs is beyond the capability of previous theoretical models. The key difference between the two cases we considered was the arc spacing. *Zhu et al.* [1994b] predicted that the spacing of multiple polar cap arcs is mainly determined by the hardness of the primary magnetospheric precipitation. A harder precipitation causes a wider spacing between individual arcs and vice versa. Our model-observation study confirms this prediction. However, the prediction can be further tested in a study by combining precipitation data from DMSP satellites with ground-based image data. The precipitation observation would define the spectral hardness that has been used as an assumed input parameter in this study.

The initial magnetospheric shear flow for both cases under

study was a simple symmetric convection shear with a single precipitation channel, but we successfully produced arcs that had multiple structures which were very similar to the observed ones. This further indicates that the observed multiple polar cap arcs may not be due to multiple structures in the magnetosphere but instead may primarily be determined by the coupled magnetosphere-ionosphere system in which the ionosphere plays an active role.

Our results show that for the multiple polar cap arcs with both narrow and wide spacings, the associated field-aligned current are mainly closed by Pedersen currents, and the Hall currents only make a small contribution. A cross flow occurs for both type of multiple arcs, but the cross flow for the arcs with a wide spacing is more spread.

In the observed arcs of case 2, the secondary arc is highly structured. To our surprise, the model developed a secondary arc with a similar fine structure. The fine structure in secondary arc for the multiple arcs with wide spacing (or hard precipitation) is a new finding. We believe this is due to the nonlinear M-I coupling process, but more theoretical analyses and modelings are needed to understand the detailed underlying physics,

This work is just one of the coordinated endeavors of the HLPS campaigns to understand the plasma structures observed in the high-latitude regions. In past years, CEDAR-HLPS campaigns have led to a very extensive observational database of polar cap arcs and many new features have been discovered. This makes quantitative model-observation studies very feasible, and they are essential for improving our understanding of polar cap arcs.
