ABSTRACT

Interactions between Nano/Micro-sized Particles and Microbes for Agricultural and
Environmental Applications

by

Li-Ting Yen, Doctor of Philosophy

Utah State University, 2024

Major Professor: Dr. Astrid R. Jacobson
Department: Plants, Soils and Climate

In semi-arid regions, high soil pH significantly limits iron (Fe) availability to plants. Metavivianite (metaVT), an iron phosphate mineral, has been utilized for Fe supplementation in plants. Previous studies have shown the effectiveness of bulk metaVT on plants grown on calcareous soil for mitigating Fe efficiency and the extremely low solubility of bulk metaVT ($K_{sp}=10^{-36}$) in electrolyte solutions, such as CaCl_2 . The cause of the discrepancy between the results of bulk metaVT under pure laboratory conditions and field application remains unclear. This study explores the applications of nano-sized metaVT (nano-metaVT) as an Fe amendment for crops, as well as using chitosan (CT) as a pH-responsive coating on the nano-metaVT amendment. This study examines the solubilities of nano-metaVT and nano-CT-metaVT in a dilute electrolyte solution and calcareous soil saturated paste extract (SPE), their impact on wheat growth in silica sand, and wheat and bean growth in a calcareous soil under salinity stress. The results indicate that key factors, such as the functional coating on the nano-fertilizers, the presence of soil microbes, and organic ligands in the soil, affect the solubilities of nano-metaVT and

nano-CT-metaVT. Moreover, beneficial soil microbes, *Pp Pf-5*, mitigate wheat abiotic stress by increasing plant transpiration. Finally, the study confirms that nano-CT-metaVT improves bean root dry mass, and the nano-metaVT treatment resulted in increased chlorophyll content in beans. Nano-metaVT demonstrates retention in the soil and lower concentrations of soluble Fe in leachates than Fe-EDDHA.

Globally, waterborne pathogens pose significant hygiene and health risks to humans. This study also investigates the disinfection efficiency of a heated oyster-shell-derived disinfectant (HOS) against *Staphylococcus aureus* and *Escherichia coli*, highlighting the critical role of singlet oxygen in bacterial inactivation. The HOS disinfectant has the potential to be applied as a universal disinfectant. Furthermore, the study studied the enhanced disinfection efficiency by the immobilization of visible-light-responsive nitrogen-doped titanium dioxide on polymethyl methacrylate (NT-PMMA). This approach shows the increased generation of singlet oxygen, hydroxyl radicals, and hydrogen peroxide with the immobilized material, demonstrating excellent reusability and maintaining a 99% disinfection rate against *Staphylococcus aureus* and *Escherichia coli* over five cycles of disinfection experiment.

PUBLIC ABSTRACT

Interactions between Nano-Micro-Particles and Microbes for Agricultural and
Environmental Applications

by

Li-Ting Yen, Doctor of Philosophy

Utah State University, 2024

Among the challenges posed by a growing global population, diminishing arable land and water resources affected by climate change are critical for enhancing crop yields, ensuring food security, and maintaining water quality and environmental health.

Iron (Fe), an essential micronutrient, is vital to plant growth. The partially oxidized form of vivianite, metavivianite (metaVT), is reported to be a promising alternative Fe fertilizer. Previous studies have shown the effectiveness of bulk metaVT on plants grown on calcareous soil for mitigating Fe efficiency and the extremely low solubility of bulk metaVT ($K_{sp}=10^{-36}$) in electrolyte solutions, such as CaCl_2 . The cause of the discrepancy between the results of bulk metaVT under pure laboratory conditions and field application remains unclear. This study explores the applications of nano-sized metaVT (nano-metaVT) as an Fe amendment for crops, as well as using chitosan (CT) as a pH-responsive coating on the nano-metaVT amendment. This study examines the solubilities of nano-metaVT and nano-CT-metaVT in a dilute electrolyte solution and calcareous soil saturated paste extract (SPE), their impact on wheat growth in silica sand, and wheat and bean growth in a calcareous soil under salinity stress. The results indicate that key factors, such as the functional coating on the nano-fertilizers, the presence of soil

microbes, and organic ligands in the soil, affect the solubilities of nano-metaVT and nano-CT-metaVT. Moreover, beneficial soil microbes, *Pp Pf-5*, mitigate wheat abiotic stress by increasing plant transpiration. Finally, the study confirms that nano-CT-metaVT improves bean root dry mass, and the nano-metaVT treatment resulted in increased chlorophyll content in beans. Nano-metaVT demonstrates retention in the soil and lower concentrations of soluble Fe in leachates than Fe-EDDHA.

Globally, disinfection methods have disadvantages, such as the high cost of raw chemicals, generation of toxic by-products, or low disinfection efficiency. It has been proposed that the disinfection observed using heated oyster-shell-derived disinfectant (HOS) is related to reactive oxygen species (ROSs) generation and protein denaturation. The findings provide evidence that cell permeability is crucial in the HOS disinfection process, and singlet oxygen plays an essential role in the disinfection mechanism. Overall, the HOS disinfectant has a high potential to be applied as a universal disinfectant and mitigate the aquaculture waste pollution problem. Furthermore, the study explores the enhanced disinfection efficiency, focusing on the NT-PMMA. NT-PMMA showed higher intensities of singlet oxygen, hydroxyl radicals, and hydrogen peroxide than NT suspension, implying the greater inactivation efficiency of immobilized NT on PMMA than in NT-suspension. The immobilization approach enhanced the inactivation performances of NT-PMMA, making it superior to NT suspension due to the absence of turbidity interference and the uniform distribution of NT.

ACKNOWLEDGMENTS

I extend my deepest gratitude to my major advisors, Drs. Astrid R. Jacobson and Yao-Tung Lin, for their invaluable assistance, inspiration, and unwavering commitment to the quality of my work. Their guidance, patience, understanding, and faith were instrumental in the successful completion of my dissertation.

My heartfelt appreciation goes to my committee members, Drs. David W. Britt, Jeanette M. Norton, Youping Sun, and Professor Joan E. McLean, for their insightful direction and contributions to this research. I am profoundly thankful to Drs. Chih-Huang Weng and Anne Anderson for their ongoing guidance on both research and writing throughout this process. I am equally grateful for the assistance and support from Drs. Paul Johnson, Simon Wang, and Scott Jones during my stay at USU. I appreciate Dr. Xin Dai for providing advice and suggestions on the statistical analysis of my results.

I also extend special thanks to the Utah Agricultural Experiment Station and the Center for Water-Efficient Landscaping (CWEL) at Utah State University, National Chung Hsing University, and the National Science and Technology Council in Taiwan for their generous funding of this research. My thanks also go to the Scholarship Committee for the awards of the Don & Ming Wang Graduate Fellowship Scholarship, the Daniel M. Teng & Lina C. Teng Endowed Fellowship, and the Southard Soil Science Graduate Fellowship. Additionally, I appreciate the National Science and Technology Council in Taiwan for the “Graduate Students Study Abroad Scholarship” (Grant ID #: 109-2917-I-005-001), which significantly supported my studies abroad.

I am sincerely grateful to my parents, Ting-Chen Yen and Min-Lien Wang, for their love and support throughout this journey.

TABLE OF ACRONYMS

Abbreviation/ acronyms	Definition
AgrM	Greenville Centennial Research Farm
AAs	Amino acids
CT	chitosan
DMA	deoxymugineic acid
DOM	dissolved organic matter
DTPA	diethylenetriaminepentaacetic acid
EPS	extracellular polymeric substances
FA	fulvic acids
HA	humic acid
HOS	heated oyster shell
ICPMS	inductively coupled plasma mass spectrometry
LMWOAs	low molecular weight organic acids
NA	nutrient agar
nano-CT-metaVT	nano-sized chitosan-coated metavivianite
nano-metaVT	nano-sized metavivianite
NB	nutrient broth
NPs	nanoparticles
<i>PcO6</i>	<i>Pseudomonas chlororaphis</i> O6
PMMA	Polymethyl methacrylate
<i>Pp Pf-5</i>	<i>Pseudomonas protegens</i> Pf-5
PW	pore water
ROS	reactive oxygen species
SOC	soil organic carbon
SOM	soil organic matter
SPEs	saturation paste extracts
TSA	tryptic soy agar
TSB	tryptic soy broth

CHAPTER 1

INTRODUCTION

With limited arable land and scarce water resources affected by climate change, it is crucial to develop more efficient fertilizers to sustainably improve crop production to feed the increasing population.¹ It has been reported that macronutrient elements, including nitrogen (N), phosphorus (P), and potassium (K), applied to the soil are lost due to leaching or becoming unavailable for plants by 40–70 %, 80–90 %, and 50–90%, respectively, causing a considerable loss of resources.² In addition, in an arid and semi-arid area, the availability of most nutrient elements, such as iron (Fe) and P, is significantly affected by high soil pH, dramatically decreasing their availability for plant uptake. Fe is a co-factor for about 140 enzymes, which participate in several metabolic processes, including photosynthesis, chlorophyll biosynthesis, and respiration.³⁻⁵ However, Fe deficiency occurs in plants cultivated in calcareous soils worldwide due to the formation of insoluble complexes in the soil.⁶ Nano fertilizers with high surface area to volume ratios exhibit properties distinct from conventional bulk fertilizers. There is a great interest in the use of nano fertilizers in order to increase fertilizer use efficiency, lower the applied dose, and minimize volatilization and leaching losses.⁷

Vivianite ($\text{Fe}^{\text{II}}(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$), a sheet structure formed by chains of octahedra and tetrahedra, is the most common stable iron phosphate mineral in reduced sediments.⁸ The partially oxidized form of vivianite, metavivianite ($\text{Fe}^{\text{II}}\text{Fe}_2^{\text{III}}(\text{PO}_4)_2(\text{OH})_2 \cdot 6\text{H}_2\text{O}$), is more common in an aerobic environment and used to provide Fe and P for plants.⁹ Previous studies have reported the potential of metavivianite as a slow-released Fe and P fertilizer.¹⁰⁻¹³ In order to prevent Fe and P applied in nutrient solutions from precipitating

or sorbing to soil solid surfaces in calcareous soils, advanced polymeric materials have the potential to form a pH-responsive coating on nano-sized metavivianite. Chitosan (CT) has been demonstrated to have beneficial influences on plant growth¹⁴, including triggering the disease-defense abilities of plants toward a wide range of plant pathogenic fungi and bacteria.¹⁵ Therefore, CT has the potential to be used as a protective coating on nano-sized metavivianite in calcareous soil.

Previous studies have demonstrated the effectiveness of bulk VT in mitigating Fe deficiency in plants grown on calcareous soils. However, other research has highlighted its extremely low solubility ($K_{sp}=10^{-36}$) in electrolyte solutions such as CaCl_2 . This discrepancy between the results observed under controlled laboratory conditions and those obtained in field applications raises questions about VT solubility and the need for further investigation to bridge this gap in understanding. This study explores the solubilities of nano-metaVT and nano-CT-metaVT in a diluted electrolyte solution (0.003 mol L^{-1} KCl) and calcareous soil saturated paste extract (SPE), which contains compounds relevant to the soil, including LMWOAs, amino acid, fulvic acid, and humic acid. The effects of the presence and absence of two model soil microbes, *Pseudomonas chlororaphis* O6 (*Pc*O6) and *Pseudomonas protegens* Pf-5 (*Pp* Pf-5), on nano-meta VT and nano-CT-metaVT are also investigated. Next, the effectiveness of nano-metaVT and nano-CT-metaVT as an Fe amendment for winter wheat (*Triticum aestivum* L.) growth in silica sand in the presence or absence of salinity stress and presence or absence of *Pp* Pf-5 are studied for salinity mitigation effect and soil microbe inoculation effect. Finally, the effectiveness of nano-metaVT and nano-CT-metaVT on monocot and dicot plants, winter wheat and bean (*Phaseolus vulgaris*), grown in calcareous soil with the presence or

absence of salinity stress is evaluated. The results can provide insight into the effectiveness of nano-metaVT and nano-CT-metaVT and the potential of being the alternative Fe nano fertilizers.

Literature review

1.1 Role of Iron (Fe) in plant health

Iron (Fe) plays a vital role in plant growth as an essential micronutrient.¹⁶ Fe is a co-factor for about 140 enzymes, which participate in several metabolic processes, including photosynthesis, chlorophyll biosynthesis, and respiration.³⁻⁵ However, Fe deficiency is common in plants cultivated in calcareous soils.⁶ It is usually recognized by yellow interveinal areas (chlorosis) in young leaves due to the alteration of chlorophyll synthesis. Fe deficiency causes economic losses through persistent leaf chlorosis and the progressive necrosis of young shoots.¹⁷ In order to respond to Fe deficiency, plants have developed two strategies to acquire the nutrient. Strategy I plants (dicots) decrease the rhizosphere pH by releasing more protons, thereby increasing Fe solubility. Strategy-I plants, such as tomato (*Solanum lycopersicum* L.) and *Arabidopsis thaliana* L., release protons via plasma-membrane-localized H⁺-ATPases to increase rhizosphere acidification and promote Fe³⁺ solubility.¹⁸ Plants then take up the reduced ferrous ion (Fe²⁺). Strategy II plants (monocots) produce phytosiderophores, a low molecular weight compound that can chelate Fe³⁺ ions and be taken up as the Fe^{III}-phytosiderophore complex by plants.^{4, 19} In addition, an adequate Fe supply is beneficial for plants by mitigating salinity stress. Rabhi et al. (2007) reported that salinity stress on *Medicago ciliaris* L. can be mitigated by adding adequate iron (30 μM Fe) to the growing

medium.²⁰ Mozafari et al. (2018) further showed that the application of iron nanoparticles (0.8 ppm) increased the content of free proline, total protein, and the enzymatic antioxidant activity of grapes (*Vitis vinifera* L. cv. Merlot 'Khoshnaw') grown under salinity stress.²¹

The disadvantages of conventional Fe fertilizers are related to the availability of Fe decreasing with increasing pH, as shown in Figure 1-1.²² Inorganic iron will be quickly rendered unavailable by reaction with hydroxide. The free Fe³⁺ concentration of soil-Fe is around 10^{-21.3} M in soil with a pH of 8, and total soluble iron is 10^{-10.2} M. However, plants require a Fe concentration of 10⁻⁶ to 10⁻⁵ M in the soil solution for optimal growth.²³

Figure 1-1. Hydrolysis species of Fe (III) in equilibrium with soil-Fe. (Modified from Lindsay, 1979)²²

Conventional amendment with synthetic Fe-chelates is currently the most effective agricultural practice for preventing Fe deficiencies in calcareous soils.²⁴ Schenkeveld et al. (2012) studied the effectiveness of Fe-EDDHA chelates under calcareous soil conditions.²⁵ In the study, the authors found a decline in Fe concentration in soil solution with all Fe-EDDHA treatments within one day, possibly due to adsorption to organic matter, Fe(hydr)oxides, and clay minerals. Moreover, the study also indicated that one of the Fe-EDDHA components, o,p-Fe-EDDHA, revealed the tendency to exchange Fe for Cu. Subsequent leaching of metals implies potential metal mobilization into the groundwater. Therefore, researchers are still looking for natural, high-purity, slow-release Fe fertilizers that are environmentally friendly.⁶ Eynard et al. (1992) revealed the effect of vivianite on alleviating Fe deficiency in chickpea (*Cicer arietinum* L.) grown in calcareous soil was competitive compared with Fe chelate (Fe-EDDHA).¹¹ Bavaresco et al. (2010) investigated the effectiveness of vivianite in alleviating the Fe deficiencies of grapes compared with iron chelate (EDDHA).²⁶ The results showed that vivianite was competitive in improving the relative chlorophyll content and yield of the grapes. Therefore, vivianite has potential as an environmentally-friendly, Fe-chelate substitute. Fathi et al. (2017) reported that the large specific surface area of nanoparticles improves chemical reaction efficiency, and the application of nano-Fe₂O₃ has positive effects on wheat under salinity stress in soil (pH 7.4-7.9).²⁷ The literature mentioned above suggests that nano-sized fertilizers could be a good source of phytoavailable Fe in soils relative to Fe-chelate.

1.2 Role of Phosphorus (P) in plant health and the application of metavivinite

Phosphorus (P) is an essential macronutrient for physiological processes during plant growth. Sufficient P improves photosynthesis, nitrogen fixation, flowering, and maturation. Mollier and Pellerin (1999) revealed the P deficiency effects on maize (*Zea mays* L. cv. Volga), such as severe reduction of leaf growth, leaf area, and root growth.²⁸ However, phosphates (e.g., $\text{H}_2\text{PO}_4^{-1}$, HPO_4^{-2} , and PO_4^{-3}) chemisorb strongly to variably-charged sites in soils so that insufficient P in soils is common and reduces crop yield globally.²⁹ Furthermore, the formation of Ca phosphates is promoted under alkaline conditions in the presence of a high Ca concentration. Thus, soluble anions ($\text{H}_2\text{PO}_4^{-1}$, HPO_4^{-2} , and PO_4^{-3}) tend to form insoluble complexes in alkaline solutions and become unavailable for plant uptake.³⁰ As shown in Figure 1-2, the solubility of calcium phosphates decreases with increasing pH. P deficiency can result in thin, spindly stems and yield losses. P deficiency influences the root exudate of plants. Carvalhais et al. (2011) showed that maize (*Zea mays* L. var. Surprise) releases a higher amount of γ -aminobutyric acid and carbohydrates under P-deficient conditions, which might affect the nutrient solubility and the attraction of rhizosphere microorganisms.³¹ Insufficient P in winter wheat (*Triticum aestivum* L) also results in the plant's vulnerability to abiotic stress, such as salt stress.³² Agriculture relies on P fertilizer inputs, and rock phosphate is the gold standard P amendment, a non-renewable resource with an estimated reserve of only 50-100 years.³³ Since P can not be synthesized, recovering and reusing P-rich sludge or sediment is critical.³³ Moreover, P leached from soils may lead to the eutrophication of surface waters, adding to global environmental/ecological problems.³⁴ It is essential to seek environment-friendly techniques for improving P bioavailability in calcareous soils.

Therefore, researchers have started investigating the application of vivianite, which can be acquired from natural resources or produced from P-rich sewage sludge or sediment, as a P amendment.³⁵⁻³⁶

Figure 1-2. Solubility of calcium phosphates compared to strengite and variscite when Ca^{2+} is $10^{-2.5}$ M or is fixed by calcite and CO_2 (g) at 0.0003 atm. (Modified from Lindsay, 1979)²²

Vivianite ($\text{Fe}^{\text{II}}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, VT) is an iron phosphate mineral that usually occurs in reduced sediments. The partially oxidized form of vivianite, metavivianite ($\text{Fe}^{\text{II}}\text{Fe}_2^{\text{III}}(\text{PO}_4)_2(\text{OH})_2 \cdot 6\text{H}_2\text{O}$, metaVT), is more common in an aerobic environment where it remains stable for extended periods of time.³⁷ Secondary sewage effluent often has a high phosphorus content.³⁸ Previous studies have demonstrated that 31% of the phosphorus in sludge can be recovered as vivianite through a chemically enhanced primary sedimentation process.³⁹ Jowett et al. (2018) also demonstrated the formation of vivianite precipitation using low-energy iron electrochemistry in sewage treatment.⁴⁰ Eshun et al. (2024) also reported a formation of biovivianite from the phosphate-solution in laboratory batch systems using two bacterial strains, *Geobacter sulfurreducens* and *Shewanella putrefaciens*.⁴¹ Schütze et al. (2020) used several kinetic models, including Elovich, Exponential, and Parabolic modes, to describe the slow release of P from bulk VT compared to hydroxyapatite and bone char in citric acid (0.01-0.1M) and CaCl_2 solution (0.01-0.1M) at a pH of 6.⁴² The authors concluded that bone char and hydroxyapatite are more sustainable P sources than bulk VT, because of the poor solubility of vivianite in CaCl_2 and citric acid solutions. However, Yang et al. (2022) demonstrated that the simultaneous release of Fe and $\text{PO}_4\text{-P}$ from the dissolution of bulk VT particles could be induced by citrate effectively at pH 6.⁴³ The authors further indicated that the enhancement of bulk VT dissolution was positively correlated to citrate concentrations, with complete dissolution observed when the citrate concentration was above 6 mM. Based on the chemical formula of VT, the application of VT as an iron amendment at a dose of 5 mg Fe per kg of soil results in a coinciding P concentration of approximately 1.85 mg kg^{-1} in the soil. This level of P supplementation is substantially

lower than what would be required to address P deficiency issues effectively. Thus, VT is primarily utilized as an Fe amendment. The application of bulk VT reduced iron deficiency in different plants, as shown in Table 1-1, including olive trees (*Olea europaea* L.)¹³ and lemon trees (*Citrus lemon* L.)⁴⁴ growing in calcareous soils. Fodoue et al. (2015) also reported the beneficial effect of applying naturally-occurring vivianite to soils in which beans (*Phaseolus vulgaris* L.) were grown, resulting in leaf densification and extension, improved root system development, and an increase in bean yield.¹² A similar study by Ayeyemi et al. (2023) also highlighted the efficacy of synthetic vivianite, noting that the shoot dry mass of wheat grown in calcareous soil (pH 8.5) treated with 135.25 mg kg⁻¹ Fe was significantly higher than that of the control.⁴⁵ It is important to note that even though the minerals applied were reported to be VT in publications, based on the authors' descriptions, they likely applied bulk metaVT. In summary, bulk metaVT, which can be recovered from sewage or wastewater, shows promise as an amendment to mitigate iron deficiencies and enhance plant growth in calcareous soils.

Table 1-1. Examples of the effectiveness of (meta)vivianite on various plants grown under high pH or calcareous conditions.

Material	Dose	Growth conditions	Plants	Effectiveness	References
vivianite	1 g/kg	pH 8.2-8.5	Chickpea (<i>Cicer arietinum</i> L.)	The chlorophyll content of chickpea leaves was improved with the application of vivianite.	11
vivianite	0.5-2 kg per tree	calcareous, pH 8.1-8.6	Olive trees (<i>Olea europaea</i> L.)	Vivianite was almost as effective as Fe chelate in reducing Fe chlorosis in olives, lasting more than two years.	13
vivianite	1.8 g/kg	calcareous, pH 8.0	Kiwifruit (<i>Actinidia deliciosa</i> (A.Chev.) C.F.Liang & A.R.Ferguson)	Vivianite enhanced leaf chlorophyll content compared to control treatment under both greenhouse and field conditions.	46
Fe sulfate, vivianite	0.08, 0.16, 0.32 g Fe kg ⁻¹	calcareous, pH value: NA	(<i>Lupinus albus</i> L.)	Vivianite improved the yield and chlorophyll content with long-term effects and was further enhanced by adding humic substances.	47
vivianite	25 g/L per pot	calcareous, pH 7.3	<i>Vitis vinifera</i> L. cv. Merlot grafted on lime-susceptible rootstock	Vivianite was as effective as Fe chelate (Fe-EDDHA) in improving the chlorophyll contents in grapevine leaves.	26
synthetic vivianite	1.0 g/kg	calcareous, pH 8.2	Rooted cuttings of <i>Vitis berlandieri</i> Resseguier No. 2 x <i>Vitis rupestris</i> Martin	The vines fertilized with vivianite had longer shoots and a higher number of leaves and exhibited higher SPAD values than the control vines. The effectiveness of vivianite lasts through 3 years, indicating the long-term fertilizing effect.	10
synthetic vivianite	0.5-2.0 g/kg	calcareous, pH 7.7	<i>Eureka lemon</i> (<i>Citrus lemon</i> L.) cuttings grafted on sour orange (<i>Citrus aurantium</i> L.)	Vivianite application exhibited a greater leaf Fe concentration and chlorophyll content than untreated plants. The effectiveness of vivianite was comparable to Fe-EDDHA .	44

1.3 Weathering of vivianite and the possible behavior in soil

The oxidation of bulk VT occurs very quickly after being exposed to air. McCammon and Burns (1980) reported the relationship between the crystal structure of bulk VT and its oxidation rate by mechanical grinding the mineral in the air, which generates heat and increases oxygen exposure to the freshly broken edges of bulk VT.⁴⁸ The study adopted a model for the oxidation of bulk VT based on experimental results and crystal-chemical principles. The authors further proposed that the $\text{Fe}^{2+}\text{-Fe}^{3+}$ pair formed after oxidation is more stable than the $\text{Fe}^{3+}\text{-Fe}^{3+}$ pair. Similar findings were also shown in Rouzies and Millet (1993) study, reporting that the concentration of Fe^{3+} in vivianite determined using Mossbauer spectroscopy remained stable at 50% for at least 375 days.³⁷ Therefore, the first oxidation stage occurs quickly, and then the structure remains stable for months before complete oxidation. When oxidation occurs, the bulk VT structure is altered due to the elimination of hydrogen bonds by converting H_2O to OH^- . In Roldan et al. (2002), the authors used either water-saturated air or 99.99% pure oxygen at a flow rate of 2 mL s^{-1} to demonstrate the formation of yellowish red (5.1 YR 5.2/6.0) lepidocrocite via complete oxidation of bulk VT.⁴⁹ Lepidocrocite ($\gamma\text{-FeO}^{3+}(\text{OH})$) is an iron oxide-hydroxide mineral that consists of layered iron (III) oxide octahedra bonded by hydrogen bonding via hydroxide layers. Weathering rates generally depend on temperature and moisture, mineral particle size, and planes of physical weakness (cleavage) in the crystal in soil. The major reaction process that weathers minerals is the dissolution of mineral-bound ions by water. Unlike the extreme conditions typically described in the literature, such as water-saturated air or 99.99% pure oxygen, the soil environment presents weaker conditions for the weathering of metaVT. In soil

environments, the oxygen availability is about 20% in the atmospheric phase, and the water content varies depending on irrigation frequency.⁵⁰ These factors contribute to relatively mild weathering conditions compared to those reported in controlled studies. Consequently, the oxidation process of metaVT in soil is likely to be slower than in the extreme conditions cited in the literature. This slower oxidation rate could influence the longevity and effectiveness of metaVT as an Fe amendment in agricultural soils.

1.4 Improving fertilizer efficiency: Nano-sizing and particle coatings

Materials that are less than 100 nanometer in size in at least one dimension are commonly known as nanomaterials.⁵¹ A substance with the size in nano-scale in one, two, or three dimensions leads to the structures including a nanosheet, a nanorod, or a nano-particles.⁵² Nano-fertilizers refer to nanomaterials utilized for supporting the nutrition of plants. The application of nano-fertilizers in crop production is attracting global interest. Current agricultural production relies on chemical fertilizers to fulfill the growing demand for food.⁵³ With limited arable land and scarce water resources affected by climate change, it is crucial that we develop more efficient fertilizers to sustainably improve crop production to feed the increasing population.¹ It has been reported that macronutrient elements, including N, P, and K, applied to the soil are lost via leaching or runoff by 40–70 %, 80–90 %, and 50–90%, respectively, causing a considerable loss of resources.⁵⁴⁻⁵⁵ Low nutrient use efficiency and over-application of chemical fertilizers may reduce crop yield and increase soil health problems.¹ Therefore, there is a great interest in applying nano fertilizers to increase fertilizer use efficiency, lower the applied dose, and minimize volatilization and leaching.⁷ With a high surface area to volume ratio, nano fertilizers exhibit distinct properties from conventional bulk fertilizers. It has been

reported that nano fertilizers modified by polymer coatings can slow down the release of nutrients, improve fertilizer utilization, and reduce leaching losses of fertilizers (Figure 1-3).⁵⁶ Therefore, the application of nano fertilizer has the potential to achieve increased sustainability in agriculture.

Figure 1-3. Nanomaterials loaded with fertilizers. (Modified from An et al., 2022)⁵⁶

Haydar et al. (2022) showed that the application of 10 mg kg^{-1} iron oxide nanoparticles in soil (pH 4.5) improved the total chlorophyll, total carbohydrates, germination rate, and iron content of mulberry (*Morus alba* L.), as well as increasing plant height, sugar content, and antioxidant enzyme contents of the leaves, compared to the control.⁵⁷ The authors further hypothesized that the probable uptake mechanism

involves the conversion of iron nano particles (FeNPs) to bio-available form ($\text{Fe}^{3+}/\text{Fe}^{2+}$) and afterward transportation towards the vascular tissues through the apoplastic or symplastic pathways. Likewise, Sabet and Mortazaeinezhad (2018) reported improvement in stem length, yield (130%), and Fe concentration (110%) in cumin (*Cuminum cyminum* L.) amended with 500–1000 mg L⁻¹ Fe as nano-iron oxide.⁵⁸ The main goals of using these nano fertilizers are to increase nutrient use efficiency and improve precision agriculture. It is generally assumed that nanoparticles of larger size (more than 20 nm) cannot penetrate through cell walls since the cell wall pore sizes vary from 2 to 20 nm.⁵⁹ However, using microscopic imaging, Ma et al. (2013) observed that nano-scale zero-valent iron (nZVI) is able to penetrate several layers of epidermal cells of cattail (*Typha latifolia* L.) and hybrid poplars (*Populous deltoids* × *Populous nigra*).⁶⁰ In addition, Serag et al. (2011) reported finding size-dependent distributions of multi-walled carbon nanotubes in the vacuole, plastid, and nucleus of Madagascar periwinkle (*Catharanthus roseus*) protoplasts using confocal imaging and TEM techniques.⁶¹ Based on these results, nano-fertilizer particle transport and translocalization in plants remain unclear. The various aspects of the uptake mechanism of nano-fertilizers result from different factors, such as the morphology of the nanoparticle and the targeted plant.

1.5 Calcareous soils: characteristics and problems

Carbonate-rich soils in the semi-arid West have characteristics rarely found in humid regions.⁶² Calcium carbonate accumulation often occurs in these soils, resulting in calcic horizon formation in the soil profile.⁶³ In addition, the cations released by mineral weathering accumulate instead of leaching out of the profile because of the low precipitation and high evapotranspiration. Therefore, the pH values of soils in arid and

semi-arid environments are generally 7 or above. The cation exchange capacity (CEC) in these soils is commonly higher than in the acid soils due to the high contents of 2:1-type clays with high amounts of permanent charge. The cations in the soil solution or the exchange sites are mainly Ca^{2+} , Mg^{2+} , K^+ , and Na^+ . Carbonate (CO_3^{2-}) and bicarbonate (HCO_3^-) generate hydroxyl ions due to the reaction with water, raising soil pH (Eq. (2) - (5)).⁶²

The availability of most nutrient elements is significantly affected by soil pH, and calcareous soils reveal the problems of low nutrient solubility. Deficiency of the macronutrient phosphorus (P) is a widespread problem in arid areas because of the low solubility of phosphates.⁶⁴ Soluble P will react immediately with Ca^{2+} and form insoluble calcium-phosphate compounds. Moreover, micronutrients, such as iron, zinc, and copper, are much less available in calcareous soil than in acid soil.⁶⁵ Fe and P deficiency in calcareous soil have been discussed in Sections 1.1 and 1.2.

1.6 Roles of organic compounds in soil rhizosphere

Plant-soil feedback is essential in plant succession, population, community structure, and diversity. Plants can change the soil microbiota by secreting bioactive molecules into the rhizosphere. Root exudates are typically comprised of primary

metabolites such as sugars, amino acids, and carboxylic acids, as well as a diverse set of secondary metabolites. Root exudate compounds affect rhizosphere microbes by acting as signaling molecules, attractants, and stimulants. Furthermore, root exudates also affect the solubility of micronutrients in soils. Awad et al. (1999) proposed the influence of phytosiderophores released from winter wheat (*Triticum aestivum* L.) on the mobilization and uptake of iron and zinc in calcareous soils.⁶⁶ The authors indicated that the production of phytosiderophores in winter wheat was enhanced under Fe deficiency, compared to Fe sufficiency.

Schütze et al. (2020) compared P release rate from vivianite, hydroxyapatite, and bovine bone char in CaCl₂ and citric acid solutions (0.01–0.1 mol L⁻¹, pH 6) over 168 h.⁴² The results showed that the released P concentrations in citric acid are 320-466-fold higher than in CaCl₂ solution, indicating the critical role of low molecular weight organic acids (LMWOAs) in the solubility of phosphate minerals. Similar results were shown in a Gypser and Freese (2020) study, reporting that the concentrations of P release from vivianite in various solutions after 1,344 h follow the order: citric acid (83.9%) > humic acid (8.1%) > CaSO₄ (1.7%) > CaCl₂ (1.4%).⁶⁷ The release of P bound by organic acids includes the processes of mineral dissolution, direct ligand exchange, and the replacement of P by organic acid anions, the formation of metal–organic complexes, and blocking of P adsorption sites.^{68, 69} The results also highlighted the critical roles of LMWOAs and AAs on the solubility of mineral in the soil solution.

Beyond these organic components, soil microbes also play a significant role in influencing solubility. Many rhizobacteria promote plant growth and protect the plant from abiotic stresses by providing access to nutrients otherwise unavailable to roots.^{70, 71}

In return, these symbiotic bacteria receive photosynthetically derived carbon in the form of sugars, amino acids, and organic acids from plant root exudates.⁷²⁻⁷⁴ Soil microorganisms, particularly plant growth-promoting rhizobacteria (PGPR), are crucial in the soil ecosystem. They colonize the rhizosphere and enhance plant health and yield through various mechanisms, including improving nutrient bioavailability and producing siderophores.⁷⁵ Some PGPR species assimilate iron by producing Fe-chelating compounds known as siderophores, which are essential for transporting iron into their cells and significantly affect the solubility of Fe fertilizers in soil solutions.⁷⁶

1.7 Salinity soil, saline irrigation water, and plant responses to salinity stress

Soil salinity is a global issue because of its negative impact on agricultural production. More than 20% of soils are salt-affected, continuously increasing owing to anthropogenic activities and climate change.^{77, 78} Natural and human activities can result in salinity problems, which might occur through pedogenetic or secondary origin due to excessive evaporation, seawater infiltration, or saline water irrigation.⁷⁸ With the global demand for water for both drinking and irrigation water increasing, competition for scarce water resources is happening worldwide.^{80, 81} Irrigating plants with recycled water that usually contains certain amounts of dissolved salts is one of the ways to ease the water demand.⁸² However, this practice may lead to salt accumulation in the soil and result in osmotic and specific ion effects on plants. For example, most sewage effluent has an EC value ranging from 0.30 to 4.7 dS·m⁻¹.³⁸ The electrical conductivity (EC) of secondary municipal effluent ranges from 0.65–0.91 dS·m⁻¹, with sodium adsorption ratio (SAR) values ranging from 3.2–7.9.^{38, 83} Excess soluble salts lower the osmotic potential of the soil water, inhibiting water uptake by plant roots and resulting in wilting.

Various indicators are used to describe salinity in the soil. The EC of the soil solution provides an indirect measurement of the salt content. Soil saturated paste extracts with ECs (EC_e) greater than $4 \text{ dS}\cdot\text{m}^{-1}$ are defined as saline, and often interfere with plant growth.⁶² SAR is an irrigation water quality parameter used in the management of sodium-affected soils, providing information on the comparative concentrations of Na^+ , Ca^{2+} , and Mg^{2+} . The SAR is also used to characterize irrigation water applied to soils. It is calculated as follows:

$$\text{SAR} = \frac{[\text{Na}^+]}{(0.5[\text{Ca}^{2+}] + 0.5[\text{Mg}^{2+}])^{\frac{1}{2}}} \quad (6)$$

where $[\text{Na}^+]$, $[\text{Ca}^{2+}]$, and $[\text{Mg}^{2+}]$ are the concentrations in mmol of charge per liter.

Salinization happens when water-soluble salts in the soil accumulate to a level that negatively affects plant growth. The excess salt accumulation obstructs the growth of crops by limiting their ability to take up water, resulting in an ion imbalance.⁸⁴ Thus, plants grown under salinity stress are impacted by osmotic stress, oxidative stress, and altered nutrient balance.⁸⁵ Ghassemi et al. (1995) reported that around 20% of irrigated lands worldwide are influenced by salt accumulation, with more than 30% of the countries in arid or semi-arid areas affected.⁸⁶ Furthermore, the United Nations reported that the global population is estimated to increase from 7.7 billion in 2019 to 11.2 billion by 2100.⁸⁷ To relieve growing population pressures, more drylands will be needed for agricultural production, which will require increased irrigation water. As sources of clean, fresh water dry up, irrigation with slightly saline water is likely, causing further soil salinization. The salinity problems of soils and irrigation water are attracting much

attention, especially in this climate change-influenced environment. It will influence the food crisis problem and the agricultural economy.⁸⁶

1.8 Advanced polymer materials in agriculture and the application of chitosan

Polymers are versatile molecules with repeating structures that can be designed to meet specific applications by modifying the composition of the replicated portion.

Examples include varying the type and/or length of side chains or adjusting their polarity or degree of crystallization. In agriculture, polymers and polymeric materials have been used to increase the efficiency of pesticides and control the delivery of agrochemicals (Figure 1-4).⁸⁸⁻⁹¹ For example, Jia et al. (2013) prepared a polydopamine film-coated controlled-release fertilizer (PCMCF) and also revealed that the polydopamine film slowed down the release of potassium (K), copper (Cu), and phosphate (P) from PCMCF in two kinds of soil.⁹¹ With the emerging development of nanotechnology, improving the bioavailabilities of nano-agrochemicals by combining the polymer techniques under specific microenvironmental conditions is critical. For instance, Liang et al. (2018) encapsulated the pesticide, avermectin, in a poly- γ -glutamic acid and chitosan polymer, forming a pH-responsive bio-nematocide nanoparticle.⁹² Poly- γ -glutamic acid and chitosan encapsulation stabilized avermectin at lower pH but allowed the release of the compound with increasing pH.

Figure 1-4. The application of functional polymers in agriculture and its benefits.

(Modified from Sikder et al., 2021)⁸⁷

Worldwide, approximately 6-8 million shrimp and crab waste shells are produced and discarded every year.^{93, 94} Chitin, a major constituent of shrimp and crab shells, is the second most abundant polysaccharide, after cellulose, in the world. Chitosan (CT), the N-deacetylated derivative of chitin, has antifungal and antibacterial properties and has been used in various applications, including cosmetics, food products, agrochemicals, pharmaceuticals, and water treatment.^{95, 96} Other studies indicate that CT benefits plant growth. It has been reported that CT treatment improves the disease-defense abilities of plants against a wide range of plant-pathogenic fungi and bacteria.¹⁵ Veroneze et al. (2020) reported that foliar application of chitosan improved the tolerance of maize against water-deficit stress.⁹⁷ Similarly, Zhang et al. (2021) reported that the 100 mg L⁻¹

chitosan foliar spray mitigated the negative effect of salinity on romaine lettuce (*Lactuca sativa* L.) and improved its growth attributes, e.g., total leaf area, shoot fresh weight, and shoot and root biomass.⁹⁸ Furthermore, Ha et al. (2019) demonstrated that the application of chitosan-encapsulated N, P, and K nano fertilizers in soil improved the yield of cucumber (*Cucumis sativus* L.) and proposed that the positive-charged surface of chitosan and K might contribute to the increased osmotic pressure of stomatal cells, leading to the increased opening of stomatal cells and greater stomatal conductance.⁹⁹

Controlled-release fertilizers are either slowly soluble, slowly released, or held in a natural organic form, compared to the “quick-releasing fertilizers” with higher water solubility. Moreover, controlled-release fertilizers release a small, steady amount of nutrients, staying in the soil longer over time. Due to the need for controlled-release fertilizers, interest in functional coatings is rising. Coating materials are selected based on their biodegrading ability, low cost, and non-toxic properties.⁸⁹ Since chitosan has all these characteristics, it has been proposed as a surface coating material. For example, Wu et al. (2008) have utilized chitosan as an external coating on an NPK fertilizer to slow its release.¹⁰⁰ Besides serving as a slow-releasing layer, chitosan coating also has the ability to promote bioavailability in calcareous soils. Chitosan-encapsulated Zn nanoparticles have been reported to promote maize (Surya local, disease susceptible)¹⁰¹ growth and alleviate the Zn deficiency in an alkaline soil and wheat (MACS 3125, durum wheat cultivars)¹⁰² in sand. However, no study has investigated the effect of the chitosan-coated Fe-P nano-amendment on plant growth and plant tolerance to salinity stress in calcareous soils.

1.9 Soil microbes - *Pseudomonas chlororaphis* O6 (*PcO6*) and *Pseudomonas protegens* Pf-5

Plant growth-promoting rhizobacteria (PGPR) are often involved in suppressing phytopathogens and have potential as biocontrol agents for the prevention of plant diseases.¹⁰³ Use of PGPR as a biocontrol agent requires complete knowledge of how they compete with and protect themselves from other organisms in the rhizosphere.

Pseudomonas chlororaphis O6 (*PcO6*) (NCBI taxonomy ID: 1037915; IMG submission ID: 54436) is a beneficial microbe isolated from the root of winter wheat by Dr. Anne Anderson. The genome properties of *PcO6* are shown in Table 1-2 and Figure B1-1. Spencer et al. (2003) examined systemic defense induction in tobacco (*Nicotiana tabacum* L.) with roots colonized by *PcO6* against two leaf pathogens, *Pseudomonas syringae* and *Erwinia carotovora*.¹⁰⁴ Later, Kim et al. (2004) also demonstrated that *PcO6* induced systemic resistance in cucumbers against the pathogen, *Corynespora cassiicola*.¹⁰⁵ *PcO6* possesses the ability to help the plant resist both biotic (pathogens) and abiotic stress (drought stress) through different mechanisms. For example, *PcO6* was reported to address drought stress in *Arabidopsis thaliana* by triggering the partial closure of stomata.¹⁰⁶ Furthermore, Dimkpa et al. (2012) reported that *PcO6* produces a pyoverdine (PVD) siderophore that is regulated by the growth phase of plants and by the presence of metal ions.¹⁰⁷ Overall, this study aims to investigate the interactions among *PcO6*, wheat plant, and nano-metaVT/nano-CT-metaVT in the soil and the impact on winter wheat grown under salinity stress.

In order to understand how the decomposition of the chitosan coating on the metaVT particles by a soil organism might affect the solubility of Fe and P, we will use a soil bacterium with the ability to produce chitinase. *Pseudomonas protegens* Pf-5 (*Pp* Pf-

5) (NCBI Taxonomy ID: 220664) is a soil-dwelling bacterium and is a known PGPR. The genome properties are shown in Table 1-3 and Figure B1-2. Loper et al. (2016) were the first researchers to verify that *Pp* Pf-5 is able to produce chitinase by genomic sequence analysis.¹⁰⁸ Rathore et al. (2020) showed that *Pp* Pf-5 inhibited pathogen growth in cumin (*Cuminum cyminum* L.) by producing chitinase, β -1, 3 glucanase, and protease.¹⁰⁹ Ruiu and Mura (2021) also revealed that the productions of *chitinase D*, *pesticin*, and the fluorescent insecticidal toxin *fitD* by *Pp* Pf-5 are key factors in bioinsecticidal action against *Musca domestica* and *Lucilia caesar* larvae.¹¹⁰ Chitinase is an enzyme that can hydrolyze chitin, which is widely distributed within insect bodies and fungal cell walls, enabling the utilization of the end products as carbon and nitrogen sources. The decomposition of chitin by chitinases is an important step in soil biogeochemical cycling of carbon and nitrogen, playing an essential role in the bactericidal and fungicidal mechanisms of *Pp* Pf-5.¹⁰⁸ Apart from chitinase production, siderophore secretion was triggered in *Pp* Pf-5 under Fe deficiency to scavenge Fe in soil (Mendonca et al., 2020).¹¹¹ Furthermore, *Pp* Pf-5 also increased root length (2.3-fold) and root mass (4.5-fold) of trembling aspen (*Populus tremuloides*, “aspen”) under low P conditions compared to non-bacterial treatments.⁷² Overall, previous studies have shown the potential of *Pp* Pf-5 to mitigate Fe and P deficiency and inhibit the growth of soil pathogens with the production of chitinase and other enzymes.

Genes assigned Pfam domains	5337	85.3%
Genes with signal peptides	647	10.34%
Genes with transmembrane helices	1448	23.14%
CRISPR repeats	-	

G+C content: guanine + cytosine content; COGs: clusters of orthologous group; CRISPR repeats: clustered regularly interspaced short palindromic repeats.

1.10 Chitinase in nature and its role

Chitinolytic enzymes have been divided into two main categories: endochitinases (EC 3.2.1.14) and exochitinases. Exochitinases have been classified into two categories, chitobiosidases (EC 3.2.1.29), which catalyze the progressive release of diacetylchitobiose from the terminal nonreducing end, and N-acetylglucosaminidases (EC 3.2.1.30) which cleaves oligomeric products obtained by endochitinases into monomers of N-acetyl glucosamine (GlcNAc). Chitinolytic enzymes can be categorized into families 18, 19, and 20 of glycosyl hydrolases based on the amino acid sequence similarity of chitinases. Family 18 comprises chitinases from viruses, bacteria, fungi, animals, and certain plant chitinases. Family 19 includes some plant chitinases and *Streptomyces* chitinases. Families 18 and 19 do not share amino acid sequence similarity and have entirely different 3D structures. Family 20 involves N-acetylglucosaminidases from bacteria, certain fungi, and humans.¹¹² Chitinase produced by various organisms plays a critical role in nature. Bacterial chitinase is able to decompose chitin and supply nitrogen and carbon as an energy source.¹¹³ Fungal chitinases are involved in the various stages of growth, including nutrition, morphogenesis, and developmental process.¹¹⁴ Insect chitinases are used to break down the old cuticle layer during the growth period.

1.11 Summary

Previous studies have indicated the key roles of Fe and P in plant growth. The application of Fe (in section 1.1) and chitosan (in section 1.8) may mitigate salinity stress on plants. Plant tolerance to salinity stress may improve with Fe, P, and chitosan supplements. A novel Fe-P amendment coated by a protective polymer, chitosan, in calcareous soils is needed. With the presence of *PcO6* and *Pp Pf-5*, the interactions

among rhizosphere, nano-metaVT, nano-CT-metaVT, and soil bacterium are essential to investigate. This study aims to synthesize nano-metaVT and nano-CT-metaVT and characterize their material properties. The Fe and P phytoavailability of nano-metaVT and nano-CT-metaVT in a dilute electrolyte solution and calcareous soil pore water (saturated paste extract) will be studied. The effects of nano-metaVT and nano-CT-metaVT on mitigating salinity stress in winter wheat grown in sand will be evaluated. Since plants have evolved two different strategies to uptake Fe, we will also investigate both a siderophore-producing monocot (winter wheat) and a rhizosphere-acidifying dicot (bush beans) to investigate whether there is a difference in their abilities to take up Fe from nano-metaVT or nano-CTmetaVT in calcareous soil.

Hypotheses:

CHAPTER 2: Exploring nano-sized metavivianite and nano-sized chitosan-coated metavivianite and their solubility in a calcareous soil saturated paste extract with soil microbe inoculation

- 1) Nano-metaVT and nano-CT-metaVT have low solubilities in KCl and SPE suspensions.
- 2) Nano-CT-metaVT is less soluble than nano-metaVT in KCl but more soluble than metaVT in SPE.
- 3) *Pp Pf-5* will increase the solubilities of nano-metaVT and nano-CT-metaVT in SPE suspensions.

CHAPTER 3: Investigate *Pseudomonas protegens* Pf-5 mitigating salinity stress in wheat grown with nano-metavivianite and nano-chitosan-coated metavivianite as Fe amendments

- 1) Fe amendment benefits *Pp* Pf-5 in ½HS suspensions under salinity stress.
- 2) Nano-metaVT and nano-CT-metaVT improve Fe uptake and mitigate the salinity stress, compared to control, in wheat grown for 14 days.
- 3) *Pp* Pf-5 improves Fe uptake and mitigates the salinity stress, compared to control, in wheat grown for 14 days.

CHAPTER 4: Exploring meta-vivianite and chitosan-coated meta-vivianite as alternative iron nano-fertilizers for plants growing in calcareous soil and the effects of salinity stress

- 1) Nano-metaVT and nano-CT-metaVT improve Fe uptake and mitigate the salinity stress in wheat and beans grown for 28 days.
- 2) Nano-metaVT and nano-CT-metaVT improve Fe uptake in beans grown to maturity (50 days).

CHAPTER 2

Synthesis of nano-sized metavivianite and nano-sized chitosan-coated metavivianite and their solubility in a calcareous soil saturated paste extract with soil microbe inoculation

2.1 Abstract

Iron (Fe) plays a critical role in the metabolic processes of plants, but its deficiency is a common issue in calcareous soils, primarily due to high pH and carbonate levels. Traditional approaches to mitigate Fe deficiency often involve the use of synthetic Fe-chelates, which are effective but have raised concerns regarding their potential for mobilization and leaching. This leaching can reduce both the efficiency and cost-effectiveness of these fertilizers as well as threaten groundwater. In response, there is growing interest in nano-sized fertilizers designed to target the rhizosphere more effectively. In this context, nano-metavivianite ($\text{Fe}^{\text{II}}\text{Fe}_2^{\text{III}}(\text{PO}_4)_2(\text{OH})_2 \cdot 6\text{H}_2\text{O}$; metaVT) has emerged as a promising alternative for Fe supplementation in plants. Previous studies have shown the effectiveness of bulk metaVT on plants grown on calcareous soil for mitigating Fe efficiency. However, other studies have reported the extremely low solubility of bulk metaVT ($K_{\text{sp}}=10^{-36}$) in dilute electrolyte solutions, such as CaCl_2 . The cause of the discrepancy in the results of bulk metaVT from pure laboratory conditions and field application remains unclear. Since the solubility of Fe in soils is strongly affected by pH and the chelation of Fe^{III} with organic ligands, the current study explores the solubility of nano-sized metavivianite (nano-metaVT) and nano-sized chitosan-coated metaVT (nano-CT-metaVT) in a diluted electrolyte solution (KCl) and a calcareous soil-saturated paste extract (SPE). SPE contains compounds relevant to the soil, including

LMWOAs, amino acid, fulvic acid, and humic acid. The effects of inoculation with beneficial soil microbes, specifically *Pseudomonas chlororaphis* O6 (*Pc*O6) and *Pseudomonas protegens* Pf-5 (*Pp* Pf-5) were also investigated. Our findings highlight the key factors that affect the solubility of nano-metaVT and nano-CT-metaVT, including the CT coating on the nano-fertilizers, the presence of soil microbes, and organic ligands. The presence of CT coating enhanced the solubility of nano-CT-metaVT in SPE suspensions. Moreover, *Pp* Pf-5 inoculation significantly influences the solubilities of both nano-metaVT and nano-CT-metaVT, increasing the total soluble Fe concentration in SPE suspensions by not only lowering the environmental pH but also involving other mechanisms, which remain unclear. The study provides insights into the potential application of nano-metaVT and nano-CT-metaVT by analyzing the characterization, solubility, and impact of soil microbe inoculation on both nano-metaVT and nano-CT-metaVT in SPE suspension.

Keywords: calcareous soil, chitosan coating, metavivianite, *Pseudomonas chlororaphis* O6, *Pseudomonas protegens* Pf-5, solubility

2.2 Introduction

Iron (Fe) is a critical micronutrient in plant growth and is involved in key metabolic processes, including photosynthesis, chlorophyll biosynthesis, and respiration. ¹⁻³ Fe deficiency frequently occurs in calcareous soils due to the rapid formation of iron hydroxides.⁴ Currently, the most common agricultural approach is to apply synthetic Fe-chelates to alleviate the Fe deficiency. However, when Hernandez-Apaolaza and Lucena (2011) evaluated the soluble and retained fractions of Fe-EDDHA in a 50-cm long soil column (sandy loam, pH 7.7), they found that over 25% of Fe-o,o-EDDHA was leached

from the soil columns within ten days.⁵ Thus, the search for eco-friendly Fe fertilizers continues.⁴ Metavivianite ($\text{Fe}^{\text{II}}\text{Fe}_2^{\text{III}}(\text{PO}_4)_2(\text{OH})_2 \cdot 6\text{H}_2\text{O}$; metaVT), a partially-oxidized iron phosphate mineral, is stable in aerobic conditions⁶ and can be recovered from phosphorus-rich secondary sewage effluent.⁷⁻⁹ MetaVT is gaining attention for its potential to supply bioavailable Fe in calcareous soils.¹⁰⁻¹²

Besides the Fe deficiency in calcareous soils, the inefficiency of nutrient use and overuse of chemical fertilizers cause problems such as diminished crop yields and soil health degradation worldwide.¹³ Nano-fertilizers have emerged as a possible solution, offering increased efficiency, reduced dosing, and minimized leaching and volatilization risks.¹⁴ Nano-fertilizers, with their high surface area-to-volume ratio, present unique properties compared to bulk fertilizers, potentially enhancing sustainable agricultural practices. Adding a functional coating on the nano-fertilizer particles is another approach to improve their utilization efficiency. Chitosan (CT) is a polysaccharide that can be extracted from crustacean shells, insect shells, and fungi and is being used in diverse fields due to its biodegradability, cost-effectiveness, and biocompatibility.^{15, 16} CT coatings can enhance nutrient release control, improve utilization, and reduce fertilizer loss, making CT an ideal coating material for nano fertilizers.¹⁷ This study modified nano-metaVT's surface with CT to provide an insoluble coating in alkaline conditions and create a positively charged surface that might enhance the retention of nano-CT-metaVT in soil.

Previous studies have highlighted the low solubility ($K_{\text{sp}} = 10^{-36}$) of bulk VT in suspension systems, such as CaCl_2 and CaSO_4 solutions.¹⁸ Interestingly, when applied to calcareous soil, bulk VT has been effective in addressing iron deficiencies in various

plants, including olive (*Olea europaea* L.) trees¹⁹ and lemon trees (*Citrus lemon* L.).¹⁰

The apparent discrepancy between the solubility in pure electrolyte suspensions and real soil applications, as reported in previous studies, may be due to the influence of organic compounds such as humic acid, fulvic acid, low molecular weight organic acids, and amino acids, which are present in soil solutions and known to impact the solubility of metals.^{20, 21}

Beyond these organic components, soil microbes also play a significant role in influencing solubility. Soil microorganisms, particularly plant growth-promoting rhizobacteria (PGPR), are crucial in the soil ecosystem. They colonize the rhizosphere and enhance plant health and yield through various mechanisms, including improving nutrient bioavailability and producing siderophores.²² Some PGPR species assimilate iron by producing Fe-chelating siderophores, which transport iron into their cells and significantly affect Fe solubility in soil solutions.²³ *Pseudomonas chlororaphis* O6 (*PcO6*) and *Pseudomonas protegens* Pf-5 (*Pp* Pf-5) are PGPRs that are reported to have several beneficial effects on plant growth and health and are known for producing the siderophore, pyoverdine (Pvd). *Pp* Pf-5 also produces the siderophore, enantio-pyochelin (E-Pch)²⁴, though it has a lower Fe affinity ($K_a = 2 \times 10^5 \text{ M}^{-1}$ for E-Pch vs. $K_a = 10^{32} \text{ M}^{-1}$ for Pvd).²⁵⁻²⁷ Moreover, Loper et al. (2016) verified by genomic sequence analysis that *Pp* Pf-5 can produce the enzyme chitinase, which degrades chitin.²⁸ This study adopted *PcO6* and *Pp* Pf-5 to compare nano-metaVT and nano-CT-metaVT solubility since they both acquire Fe and have the ability to produce siderophores. In addition, *Pp* Pf-5 has been reported to produce chitinase, which might affect the CT coating by decomposing chitosan, then alter the solubilities of nano-metaVT and nano-CT-metaVT.

In summary, several key aspects of nano-metaVT and nano-CT-metaVT are yet to be fully understood, including 1) the influence of CT coating on solubility of nano-metaVT, 2) the impact of organic compounds relevant to soil on solubilities of nano-metaVT and nano-CT-metaVT, and 3) the effects of soil microbe inoculation, on solubilities of nano-metaVT and nano-CT-metaVT. The SPE-suspension system is used to investigate the key factors that might affect the solubilities of the nano-metaVT and nano-CT-metaVT. We hypothesize that nano-metaVT and nano-CT-metaVT have low solubility in KCl and SPE suspensions. Moreover, nano-CT-metaVT is less soluble than nano-metaVT in KCl but more soluble than nano-metaVT in SPE because of the characteristics of CT coating. Lastly, Pp Pf-5 and P_cO₆ affect the solubilities of nano-metaVT and nano-CT-metaVT in SPE suspensions. This investigation aims to gain insight into the preliminary application of nano-metaVT and nano-CT-metaVT and the potential effects of soil-dwelling microbes.

2.3 Materials and Methods

2.3.1 Chemical reagents

Monoammonium phosphate [(NH₄)H₂PO₄], iron (II) sulfate heptahydrate (FeSO₄·7H₂O) (ACS reagent, ≥ 99.0%), and chitosan (from shrimp shells, ≥ 75% deacetylated) were purchased from MilliporeSigma (Burlington, MA, USA). Sodium hydroxide (NaOH) was purchased from Mallinckrodt (UK). All reagents used in this study were reagent grade or better.

2.3.2 Synthesis of nano-metaVT and nano-CT-metaVT

Nano-metaVT was synthesized based on the protocols described by Ammari and Hattar (2011).¹⁰ The synthesis was conducted in an ice bath in an argon gas chamber to eliminate oxygen and allow ferrous ions to be present. Five-gram monoammonium phosphate $[(\text{NH}_4)\text{H}_2\text{PO}_4]$ was dissolved in 200 mL deionized water to form a solution with a PO_4^{3-} concentration of 0.217 mol L^{-1} . After stirring for 30 min, 15 g ferrous sulfate ($\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$) was slowly added to the solution to create a solution with a Fe concentration of 0.270 mol L^{-1} . The solution was kept stirring for 30 min. Then, the pH of the suspension was adjusted to pH 6.5 by dropwise additions of $0.00125 \text{ mol L}^{-1}$ NaOH. A pale-blue, vivianite precipitate was washed several times with deionized water until the EC of the mixture was below $0.2 \text{ dS} \cdot \text{m}^{-1}$. The precipitate was then centrifuged at $6,000 \times g$ for 15 min, the supernatant liquid decanted, and the pellet dried in a freeze-dryer (FreeZone Benchtop Freeze Dryer, Labconco, Kansas City, MO, USA).

A chitosan (CT) solution was prepared by dissolving one gram of CT in 200 mL 0.1 mol L^{-1} acetic acid (CH_3COOH) while stirring. After 12 h, four grams of metavivianite powder was slowly added to the CT solution and stirred for an additional 30 min. The pH of the suspension was adjusted to 6.5 by adding $0.00125 \text{ mol L}^{-1}$ NaOH. The nano-CT-metaVT precipitate was then rinsed with deionized water until salt-free ($< 0.2 \text{ dS} \cdot \text{m}^{-1}$). Finally, the precipitate was centrifuged at $6,000 \times g$ for 15 min, the supernatant liquid was decanted, and the pellet freeze-dried.

2.3.3 Nano-MetaVT and nano-CT-metaVT characterization

2.3.3.1 Particle thickness, morphology, and elemental presence

The nano-metaVT and nano-CT-metaVT powders were fixed onto aluminum stubs for scanning electron microscopy (SEM) analysis using copper tape. The samples were sputter-coated with a 10-nm layer of gold and palladium using a rotary sputter coater system EMS150R ES (Electron Microscopy Sciences, Hatfield, PA, USA). The morphology and the thickness of the particles were viewed with a SEM (Quanta FEG 650, Field Electron and Ion Company, Hillsboro, OR, USA) under a high vacuum at an accelerating voltage of 20 kV. The thickness of the nano-metaVT and nano-CT-metaVT crystals was measured with image processing software (Image J, version 1.53). Three images each were used to measure the thickness of nano-metaVT and nano-CT-metaVT when viewed at ten random locations. The instrument was equipped with energy-dispersive X-ray spectroscopy (EDS, Oxford Instruments, Abingdon-on-Thames, UK) using an X-Max detector at an accelerating voltage of 5 kV to identify elements present.

2.3.3.2 Zeta potential

The zeta potentials of the nano-metaVT and nano-CT-metaVT particles were measured using an electrophoretic light scattering instrument (Zetaplus, Brookhaven Instruments Corporation, Holtsville, NY, USA). Samples were prepared in 0.0001 mol/L KCl, forming a 0.4 g L⁻¹ suspension, and analyzed at 25 °C in triplicate.

2.3.3.3 Crystalline structure

X-ray diffraction (XRD) patterns were obtained using X-ray Diffractometers. The 0-year nano-metaVT and nano-CT-metaVT were analyzed at Utah State University

(Panalytical X'Pert Pro X-ray diffraction spectrometer, Malvern Panalytical, Malvern, UK), and 1-year and 2-year nano-metaVT and nano-CT-metaVT were analyzed at the University of Utah (D8 Discover diffraction spectrometer, Bruker, Billerica, MA, USA). The fine nano-metaVT and nano-CT-metaVT powders were kept on a zero-diffraction plate for analysis. XRD data were collected with a 2θ diffraction angle from 20° to 80° , with a 0.02° step size, 0.4 seconds per step count time.

2.3.3.4 Elemental analysis

The N, C, H, and O compositions of the nano-metaVT and nano-CT-metaVT nanoparticles were analyzed with an elemental analyzer (Vario EL cube, Elementar, Cheadle, UK). A 1–1.5 mg sample was packed into a tin capsule and placed in the automated sampler of the device. The sample was burned in a flow of oxygen at temperatures up to 1200°C . The gases formed were successively passed through oxidizing and reducing tubes and adsorption columns, each of which was intended to identify the gas mixture components (CO_2 , H_2O , and SO_2).

2.3.3.5 Surface analysis

To identify nano-metaVT and nano-CT-metaVT surface elements, X-ray photoelectron spectroscopy (XPS) was performed with a photoelectron spectroscopy system (PHI 5000 Versa Probe II, ULVAC-PHI, Kanagawa, Japan). Monochromated $\text{Al K}\alpha$ (1486.6 eV) radiation with an operating power of 50 W (15 kV voltage) was used for all the XPS measurements. The XPS survey spectra were measured with a pass energy of 117.4 and 0.125 eV energy steps. For the measurement of each atomic element, a pass energy of 23.5 with 0.025 eV energy steps was used.

2.3.3.6 Specific surface area

The specific surface area was analyzed by nitrogen adsorption according to the Brunauer-Emmett-Teller (BET) equation (ASAP 2020, Micromeritics, Norcross, GA, USA). The de-gas temperature was set at 60 °C for 12 h (Colombo et al., 2017; Oliveira et al., 2017).

2.3.4 Characterization of soil

A Millville series soil (coarse-silty, carbonatic, mesic Typic Haploxerolls) soil was used in this study. The soil (0–10 cm depth) was collected from USU Greenville Research Farm in North Logan, UT, USA, in April 2020, from conventionally managed wheat breeding plots irrigated and planted in a wheat-alfalfa rotation. We refer to the soil as AgrM (Agricultural Milleville) in this article and previous publications.²⁹⁻³¹ The soil characteristics, including soil texture, particle size distribution, pH, EC, organic matter content, calcium carbonate equivalent, dissolved organic carbon (DOC), cation exchange capacity, phosphorus, potassium, ammonium, nitrate, sulfate, and other element concentrations were analyzed using Standard Methods for the Western Region.³² Soil characteristics are provided in Table 2-1. The AgrM soil is not typically characterized as Fe-deficient, with a DTPA-extractable Fe concentration of 6 mg kg⁻¹ soil, which is above the generally recommended Fe level of 5 mg kg⁻¹ soil for winter wheat. However, Gerwing and Gelderman (2023) noted that Fe deficiencies can become more pronounced when the soil is wet and cold.³³ Therefore, a DTPA-extractable Fe concentration close to the recommended dose, may still be marginal for crops particularly sensitive to Fe deficiency, like beans, or seasonally following early spring snowmelt.

Table 2-1. Characteristics of soil sampled from 0–10 cm.

Characteristics	
Location	N 41.76346° W 111.81396°
Elevation	1369 m
Soil abbreviation	AgrM
Soil series, texture	Millville, silt loam
Taxonomic class	Coarse-silty, carbonatic, mesic Typic Haploxerolls
Particle size distribution (% sand/silt/clay)	22/56/23
Management	Irrigated commercial-style production
Crops	Winter wheat and small grain breeding trials in rotation with alfalfa
pH _{saturated paste extract}	8.4

2.3.5 Preparation and characterization of soil saturated paste extracts (SPE)

About 90 mL double-deionized water (resistance >18 M Ω cm) was added to 250 g soil in a 250 mL polycarbonate centrifuge bottle (Nalgene™) to form a saturated paste. The mixture was mixed well with a spatula and allowed to stand for 18 hours. Then water was added as necessary, and the soil paste was centrifuged at 4,608 \times g for 25 min. The supernatant was filtered through a 25 mm nylon syringe filter with a pore size of 0.22 μ m (Thermo Scientific, Waltham, MA, USA). Characteristics of the SPE after 0.2-micron filter sterilization are presented in Tables 2-2, 2-3, and 2-4. The cations were analyzed by an inductively coupled plasma mass spectrometer (Agilent 7700x, Agilent Technologies, Santa Clara, CA, USA). Anions were analyzed by ion chromatography (Dionex method 123) with a Dionex ICS-3000 (ThermoFisher Scientific). Amino acids (AAs) were analyzed by liquid chromatography triple quadrupole mass spectrometry (LC-QqQ-MS) (Agilent 1290 LC coupled with Agilent 6490 QqQ-MS, Agilent Technologies, Santa Clara, CA, USA) with an Imakt amino acid column (50 \times 3 mm). Soluble elements were analyzed using the EPA method 6020 on an inductively coupled plasma mass spectrometer (Agilent 7700x, Agilent Technologies, Santa Clara, CA, USA).

2.3.6 Solubility of nano-metaVT and nano-CT-metaVT in a suspension system

This experiment evaluated the solubilities of nano-metaVT and nano-CT-metaVT in a dilute KCl solution and SPE. *PcO6* is a soil bacterium isolated from field-grown winter wheat in Logan, Utah. *Pp Pf-5* (ATCC BAA-477) was purchased from the American Type Culture Collection (ATCC). All the experiments were conducted in a continuous suspension system on a shaker table. Measurements for each sample bottle and structured were collected daily using a randomized complete block design (RCBD) with three trials (block) per treatment. Each trial (block) contained three replicates, yielding nine experimental units ($n = 9$). s

The variables were KCl electrolyte/SPE, nano-metaVT/ nano-CT-metaVT, and the presence/absence of *PcO6/Pp Pf-5* in SPE. The 0.003 mol L^{-1} KCl solution was autoclaved, and SPE was filter-sterilized through a $0.2 \mu\text{m}$ nylon filter. The doses of nano-metaVT and nano-CT-metaVT were 0.6 g L^{-1} in solution based on total particle mass. We calculated the amount of mass CT contributes to the overall mass from the particle digestion results. The result shows that CT contributes about 1.8% of the overall mass of nano-CT-metaVT. In the treatments with soil microbes, *PcO6* and *Pp Pf-5* were added to the 99 mL KCl electrolyte or SPE as 1.0 mL aliquots of a $2 \times 10^6 \text{ CFU mL}^{-1}$ bacterial suspension. The final bacterial concentration was about $2 \times 10^4 \text{ CFU mL}^{-1}$. All the reaction suspensions in sterile polypropylene 250-mL bottles were placed in a cardboard box on an end-to-end shaker and kept shaking at 100 rpm in the dark throughout the reaction process. At each sampling time point (0, 1, 2, 3, 4, 5, 6, and 7 days), each bottle was placed on a magnetic stirrer and mixed to keep the particles in suspension. One mL of the sample with *PcO6/Pp Pf-5* treatments was series-diluted and

cultured on Luria–Bertani agar (LB) or tryptic soy agar (TSA) plates, respectively, to verify the bacterial concentrations. Then, a 10 mL suspension was placed in a polyallomer centrifuge tube (Nalgene™, Thermo Fisher Scientific, Waltham, MA, USA), and pH and EC were measured. Then, the suspension was centrifuged at $20,800 \times g$ for 30 minutes to remove the particle larger than 30 nm, filtering through a 25 mm nylon syringe filter with a pore size of 0.22 μm (Thermo Scientific) and acidifying to 0.5% HNO_3 . Since the particle sizes of both nano-metaVT and nano-CT-metaVT are micro-sized in two dimensions and nano-sized in one dimension, the centrifugation and filtration processes likely removed any nano-metaVT and nano-CT-metaVT particles. Finally, the total soluble Fe and P concentrations of the samples were analyzed by an inductively coupled plasma mass spectrometer (Agilent 7700x, Agilent Technologies).

2.3.7 Geochemical modeling

We used the geochemical speciation software, Visual MINTEQ Ver. 3.1³², to investigate the comparison between the experimental and predicted solubility, the potential chemical complexes in SPE suspension, and how pH changes affect VT solubility predicted by the software. Both FA and HA were simulated using the NICA-Donnan FA/HA model, which is an integral component of Visual MINTEQ Ver. 3.1. Sparks (2023) previously expanded the geochemical database's stability constants, which were taken into account.³⁰ The composition of the SPE served as the basis for the model's input solution phase. This simulated solution phase was then employed to predict potential ligand complexes in the SPE. The input information is shown in Table 2-4.

Table 2-4. The input in the geochemical modeling for vivianite-KCl and vivianite-SPE solubilities and potential chemical complexes prediction.

Input	Values
Solution	KCl
pH	pH value measured on Day 7
Ionic strength	To be calculated
CO ₂	42 ppm
Total soluble elements	Table B2-1
Finite solid	Vivianite 0.001196 mol/L
Settings	Oversaturated solids are not allowed to precipitate (Exceptions: Solid specified as infinite, finite, or possible)
Solution	SPE
pH	pH value measured on Day 7
Ionic strength	To be calculated
CO ₂	42 ppm

Volume of solution to be titrated	100 a.u.
Volume of titrant	0.1
Concentration unit of titrant	mol L ⁻¹
Titrant composition	0.1 mol L ⁻¹ HNO ₃

2.3.8 Data Analyses

We evaluated the changes in pH, EC, and total soluble Fe and P concentrations over time under each treatment using a mixed-effects model with repeated measures. In the mixed model treatment, time and its interactions are fixed effects, while block is a random effect. Correlations among the repeated measurements were estimated with compound symmetry structure. The rate of change (slope) due to time was estimated for each treatment and compared. Treatment difference at each experimented time point was also tested for significance. The significance level was set at 0.05. Diagnostics of residuals did not reveal a departure from normality and nonconstant variances. All statistical analyses were performed using SAS® Studio (release 3.81, SAS Inc., Cary, NC, USA).

2.4 Results and Discussions

2.4.1 Characterization of nano-metaVT and nano-CT-metaVT

The X-ray diffraction (XRD) patterns of nano-metaVT and nano-CT-metaVT are depicted in Figs. 2-1a and 2-1b, showing distinct major diffraction peaks. These peaks occur at 2θ angles of 11.2° , 13.2° , 18.1° , 19.4° , 23.1° , 27.8° , and 29.9° and correspond to the (110), (020), (200), (-101), (101), (031), and (-301) crystal faces of $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$. These data confirm the crystalline nature and specific crystallographic structure of the nano-metaVT and nano-CT-metaVT materials. Repeated XRD analyses of the nano-metaVT and nano-CT-metaVT particles at the end of all the experiments (0, 1, and 2 years) reveal no significant changes in particle composition. As shown in Fig. 2-1c and 1d, SEM images reveal that nano-metaVT and nano-CT-metaVT particles possess feather-like structures comprising a multilayered, nano-plate composite. The specific surface area of nano-metaVT and nano-CT-metaVT are 13.9 and $14.5 \text{ m}^2 \text{ g}^{-1}$, respectively. To analyze these structures further, ten spots on the nano-plates were randomly selected for thickness measurements. The measurements were conducted using Image J software (version 1.53). The analyses show that the average thickness of the nano-plates in nano-metaVT is $24.9 \pm 5.4 \text{ nm}$, while for nano-CT-metaVT, it is $38.9 \pm 7.6 \text{ nm}$. The increased thickness of the nano-CT-metaVT is attributable to the chitosan coating, which adds to the overall dimensions of the nano-plates.

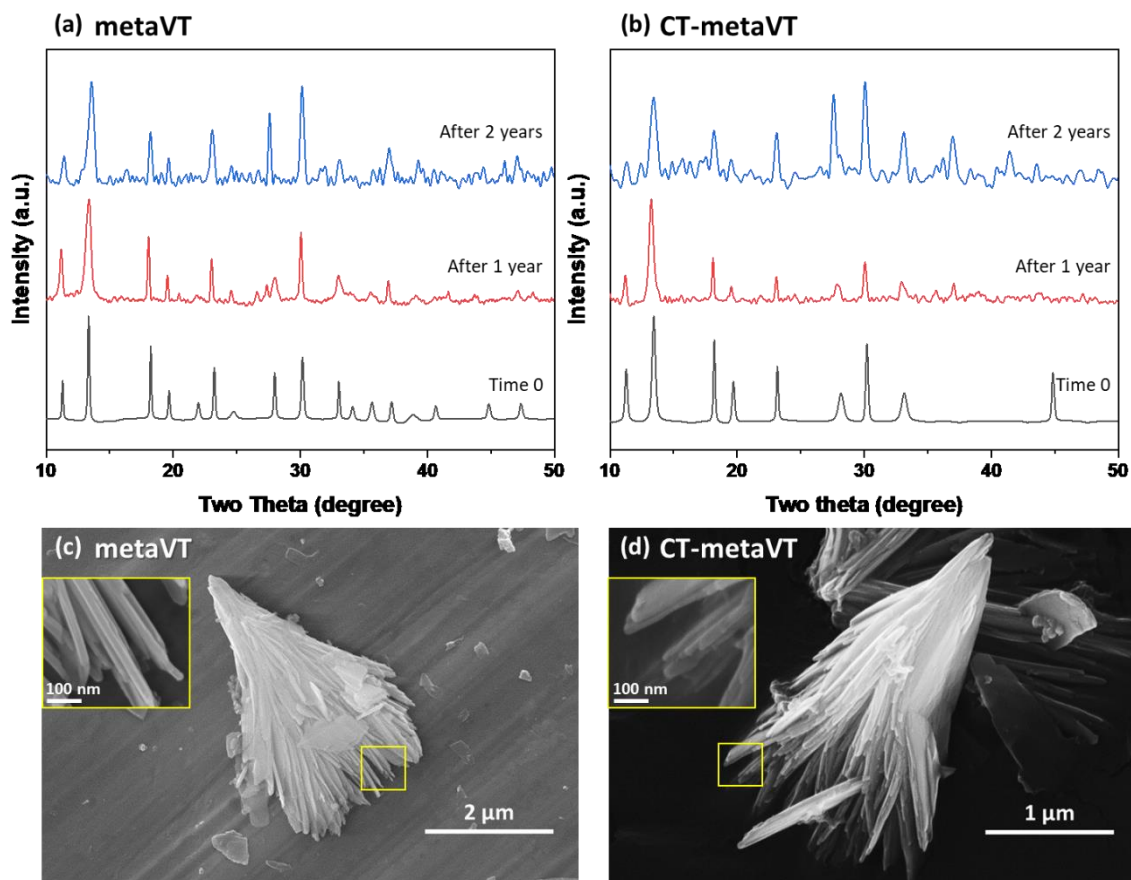

Figure 2-1. XRD pattern of nano-metaVT (a) and nano-CT-metaVT (b) analyzed at different times (0, 1, and 2 years). The 0-year samples were analyzed at Utah State University (Panalytical X'Pert Pro X-ray diffraction spectrometer, Malvern Panalytical Ltd, England), and 1-year and 2-year samples were analyzed at the University of Utah (D8 Discover diffraction spectrometer, Bruker, Billerica, MA, USA). SEM images of nano-metaVT (c) and nano-CT-metaVT (d) were observed after being freeze-dried.

Table 2-6 presents the analyses of nitrogen (N), carbon (C), hydrogen (H), and oxygen (O) in the studied materials. It is observed that nano-CT-metaVT exhibits an approximately 2.3 times higher N content and 21.8 times higher C content than uncoated nano-metaVT. This significant increase in the N and C contents of nano-CT-metaVT can be attributed to the presence of glucosamine in the CT coating. Additionally, surface charge measurements reveal that nano-metaVT displays a negatively charged surface, with a zeta potential of -14.6 ± 5.6 mV, whereas nano-CT-metaVT exhibits a positively charged surface of 22.0 ± 2.8 mV. This difference in the surface charges of the two particles further supports that CT coated the nano-metaVT surface. The design of nano-CT-metaVT, with its positively charged surface, is intended to enhance its persistence in a soil environment through electrostatic attraction to the typically negatively charged soil particles. This characteristic could be critical for the prolonged availability of nutrients in the soil and to slow potentially high leaching rates. Furthermore, the CT coating on the nano-CT-metaVT may serve as a carbon source for soil microorganisms, potentially influencing the subsequent microbial degradation processes in the soil ecosystem. This aspect of the nano-CT-metaVT particles could have significant implications for its role in nutrient cycling and soil health.

Table 2-6. N, C, H, and O contents and the zeta potential of nano-metaVT and nano-CT-metaVT.

	Elemental analysis (%)				Zeta potential (mV)
	N	C	H	O	
nano-metaVT	0.14	0.06	2.26	22.90	-14.6 ± 5.6
nano-CT-metaVT	0.32	1.31	2.59	24.61	22.0 ± 2.8

The results from the XPS and zeta potential analyses provide compelling evidence for the presence of a CT coating on nano-metaVT. These methods effectively identify the surface chemical composition and the positive surface charge characteristic of the chitosan coating. The specific XPS signals of the N 1s region, presented in Fig. 2-1a, elucidate peaks at 399.0–399.3 eV, corresponding to the assignments of -NH₂ and NH groups, respectively.^{34, 35} Fig. 2-2b displays the XPS signals of the Fe 2p region for both nano-metaVT and nano-CT-metaVT and the peak of Fe 2p_{3/2} at 711–712 eV, which indicates that both Fe²⁺ and Fe³⁺ are present in the nano-metaVT and nano-CT-metaVT.³⁶ In Fig. 2-2c, the observable peaks at 135 eV are attributed to P-O.³⁷ These Fe 2p₃ and P 2p spectra reveal an overall higher intensity of Fe and P signals for nano-metaVT compared to nano-CT-metaVT. This difference in signal intensity can be attributed to the variation in surface composition due to the CT coating. This reduction in spectral intensity suggests a screening effect caused by the CT coating. In essence, the presence of the CT layer on the surface of the nano-metaVT particles partially obscures the underlying Fe and P elements, leading to a diminished intensity in their respective spectral peaks.

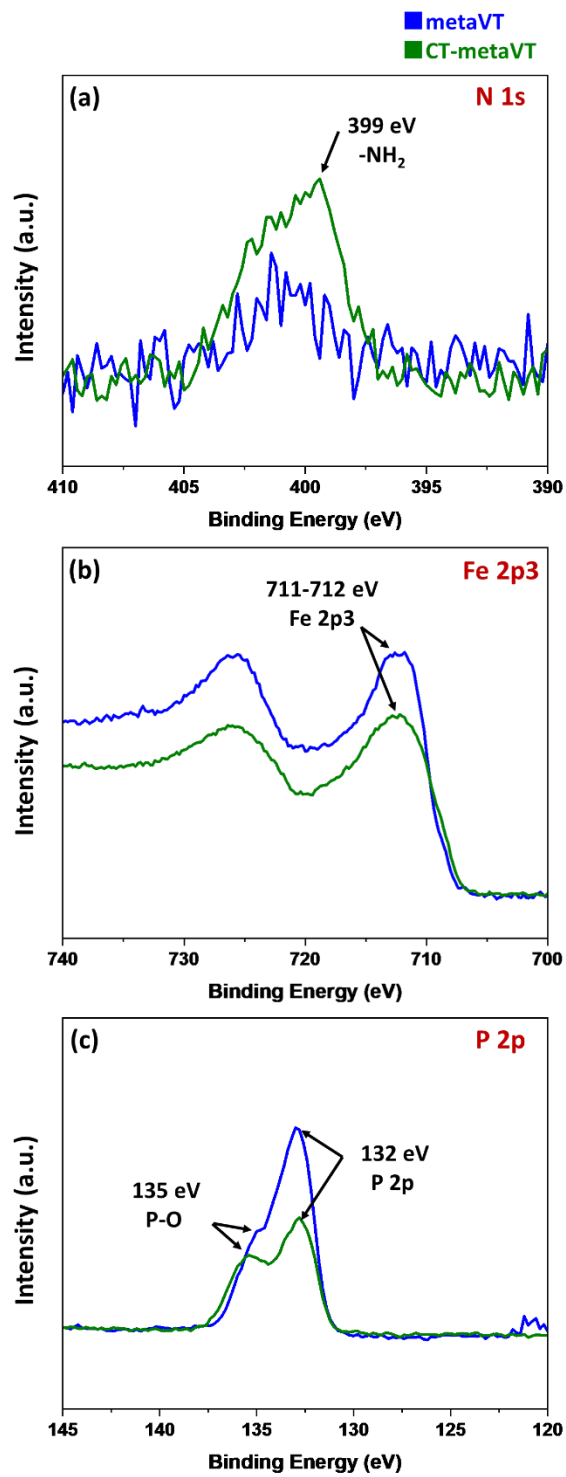

Figure 2-2. XPS spectra of N 1s (a), Fe 2p3 (b), and P 2p (c) in nano-metaVT and nano-CT-metaVT.

2.4.2 Solubility of nano-metaVT and nano-CT-metaVT

2.4.2.1 Solubility in KCl and SPE suspensions

The solubility of Fe in soils is strongly affected by pH and the chelation of Fe^{III} with organic ligands. In this experiment, a dilute electrolyte solution was prepared with KCl at the same EC as the SPE, 0.4 dS·m⁻¹. The differences between the KCl and SPE solutions include chemical composition and pH. The SPE solution contains the soluble components extracted from the soil solution with a pH_{saturated paste extract} of 8.4, while the KCl solution was prepared at a concentration of 0.003 mol L⁻¹ at a pH of 5.9. The kinetic results over seven days were analyzed with a generalized linear mixed model, and the slope and the intercept are attached to a table in the graph. The total soluble Fe concentrations of both nano-metaVT and nano-CT-metaVT in the KCl suspension (pH 5.9) increase from 683 to 1,146 and 527 to 654 µg L⁻¹, respectively (Fig. 2-3a). The total soluble Fe concentrations in the nano-metaVT-KCl suspensions are significantly higher over time, with a slope of 57.6, greater than that of the nano-CT-metaVT-KCl suspensions (23.3). This difference can be attributed to the solubility characteristics of CT, which is known to dissolve in dilute acidic solutions below a pH of 6.0, as noted by Rouhani Shirvan et al. (2019).³⁸ Even though the pH of the 0.003 mol L⁻¹ KCl solution is 5.9, CT becomes soluble, yet it is only partially protonated under this condition. Moreover, the total soluble Fe concentrations of nano-metaVT and nano-CT-metaVT in the SPE suspensions (Fig. 2-3b) are significantly lower, about 30 µg L⁻¹, in SPE suspension (pH 8.4) compared to Fe solubility in the KCl suspensions and remain stable throughout the reaction period.

The total soluble P concentrations in the nano-metaVT-KCl and nano-CT metaVT-KCl suspensions also increase over time from 302 and 310 $\mu\text{g L}^{-1}$ to 630 and 698 $\mu\text{g L}^{-1}$, respectively. Total soluble P concentrations in both the nano-metaVT and nano-CT-metaVT suspensions increase over time in KCl (Fig. 2-3c) but not in the SPE suspensions (Fig. 2-1d). Schütze et al. (2020) found that P release from vivianite in calcium chloride (CaCl_2) suspensions (0.01 mol L^{-1} , pH 6) reached 0.0005 mg m^{-2} in 168 h.³⁹ By comparison, under similar pH conditions (pH 5.9) but a lower electrolyte concentration (0.003 mol L^{-1} KCl), our nano-metaVT and nano-CT-metaVT suspensions exhibited higher total soluble P concentrations of 0.076 and 0.080 mg m^{-2} , respectively, representing a 152-160 fold increase on a specific surface area basis. Additionally, on a weight basis, while only 0.02 mg P is dissolved from each gram of VI according to Schütze et al., 1.05 and 1.17 mg P are dissolved from each gram of nano-metaVT and nano-CT-metaVT in our study, equating to 53-59 times higher solubility. Still, the experimental conditions in Schütze et al.'s (2020) study are not identical to those in the current research, and some factors might affect the solubility, such as the ionic strength of the solution and mineral crystallinity. However, the results suggest a possible nano-size effect, resulting in the increased solubility of the nano-sized metaVT and CT-metaVT over bulk VT.

The pH and EC of the suspensions were measured daily, and the findings are presented in Fig. 2-4. While the nano-metaVT-KCl suspension displays higher total soluble Fe concentrations than the nano-CT-metaVT-KCl suspension (Fig. 2-3a), the pH of the nano-metaVT-KCl suspension is consistently lower (Fig. 2-4a). Similarly, the nano-CT-metaVT-SPE suspension exhibits higher total soluble Fe concentrations and

lower pH than those in nano-metaVT-SPE suspension (Fig. 2-3b). The results reflect the proton release during the hydrolysis processes of both nano-metaVT and nano-CT-metaVT suspensions (Eq. (1) - (4)). The initial decrease in pH observed from day 0 to day 2 in both nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions, as shown in Figure 2-4b, followed by a subsequent increase, suggests that the protons released during the hydrolysis process are being buffered by the hydroxyl groups present in the SPE suspensions. No significant differences in EC were observed between the nano-metaVT and nano-CT-metaVT suspensions, as indicated in Figures 2-4c and 2-4d.

Although the chelation and complexation of organic compounds in SPE were expected to enhance the solubility of both nano-metaVT and nano-CT-metaVT compared to the KCl suspension, this was not the case. Moreover, the nano-CT-metaVT-SPE demonstrated higher total solubility than the nano-metaVT-SPE, although both were significantly lower than their respective solubilities in the nano-CT-metaVT-KCl and nano-metaVT-KCl suspensions. This observation suggests that the interactions influencing solubility in SPE suspensions, containing compounds relevant to the soil, including LMWOAs, amino acid, fulvic acid, and humic acid, may differ substantially from those in KCl suspensions, a dilute electrolyte solution.

Figure 2-3. Total soluble Fe concentration in 0.003 mol L^{-1} KCl suspension (a) and SPE suspension (b). Total soluble P concentration in 0.003 mol L^{-1} KCl suspension (c) and SPE suspension (d). Condition: [nano-metaVT/ nano-CT-metaVT] = 0.6 g L^{-1} . Baseline: The initial total soluble Fe and P concentrations in SPE before adding the treatment.

Figure 2-4. The pH of 0.003 mol L⁻¹ KCl suspension (a) and SPE suspension (b) changed over time. The EC of 0.003 mol L⁻¹ KCl suspension (c) and SPE suspension (d) changed over time. Condition: [nano-metaVT/ nano-CT-metaVT] = 0.6 g L⁻¹. Baseline: The initial pH and EC of SPE before adding the treatment.

2.4.2.2 *PcO6* inoculation effect

To investigate the impact of soil microbes on the solubility of nano-metaVT and nano-CT-metaVT, suspensions containing these nanoparticles in SPE were inoculated with beneficial soil microbes known for Pvd production and incubated for seven days. The specific microbe studied first was *PcO6*. The concentrations of total soluble Fe and P in both nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions inoculated with *PcO6* are depicted in Fig. 2-5. Analysis using a generalized linear mixed model reveals no significant difference in the slope or intercept of total soluble Fe concentrations between the *PcO6* and the no-microbe treatments for the nano-metaVT-SPE suspension (Fig. 2-5a). However, in the nano-CT-metaVT-SPE suspension, the *PcO6* treatment results in a higher total soluble Fe concentration than the no-microbe treatment. The total soluble P concentrations are not significantly influenced by *PcO6* inoculation in either the nano-metaVT-SPE (Fig. 2-5c) or nano-CT-metaVT-SPE (Fig. 2-5d) suspensions.

Interestingly, the pH levels in the nano-CT-metaVT-SPE suspension inoculated with *PcO6* are consistent with those in suspensions without *PcO6* treatment (Fig. 2-6b). This observation contrasts with the results from Figs. 2-4a and 2-4b, indicating that while the *PcO6* treatment increased total soluble Fe in the nano-CT-metaVT-SPE, it did not significantly affect the pH. Additionally, no significant differences in EC were observed between the nano-metaVT and nano-CT-metaVT suspensions (Figs. 2-6c and 2-6d). These findings suggest that the impact of *PcO6* on Fe solubility is specific to the nano-CT-metaVT under the conditions tested without affecting the overall pH or EC of the suspensions.

Figure 2-5. Effects of *PcO6* inoculation on total soluble Fe concentrations in nano-metaVT-SPE (a) and nano-CT-metaVT-SPE (b) suspensions. The effects of *PcO6* inoculation on total soluble P concentrations in nano-metaVT-SPE (c) and nano-CT-metaVT-SPE (d) suspensions. Baseline: The initial total soluble Fe and P concentrations in SPE before adding the treatment.

2.4.2.3 *Pp* Pf-5 inoculation effect

Pp Pf-5, recognized as a plant PGPR, is notable for its ability to protect plants by producing a variety of siderophores and enzymes. This bacterium synthesizes several types of siderophores, including Pvd and E-Pch, with E-Pch being a yellow-green siderophore that is structurally distinct from Pvd and exhibits a lower affinity for Fe.^{24, 40,}
⁴¹ Loper et al. (2016) have also reported that *Pp* Pf-5 produces chitinase, an enzyme that breaks down chitin found in insect exoskeletons and fungal cell walls, thus facilitating the use of these degradation products as carbon and nitrogen sources.²⁸

Figs. 2-7a and 2-7b illustrate that inoculation with *Pp* Pf-5 significantly enhances the total soluble Fe concentrations in both nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions compared to the no-microbe treatment. Specifically, *Pp* Pf-5 inoculation resulted in intercept values 22.5- and 29.1-fold higher than those of the no-microbe treatments in the nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions, respectively. However, the levels of soluble P remained unchanged with *Pp* Pf-5 inoculation in both types of suspensions (Figs. 2-7c and 2-7d).

Furthermore, the pH levels in the suspensions inoculated with *Pp* Pf-5 are higher than those without the bacterium (Figs. 2-8a and 2-8b). This aligns with earlier findings (Figs. 2-4a and 2-4b). Additionally, the EC values are lower in both nano-metaVT and nano-CT-metaVT suspensions treated with *Pp* Pf-5 (Figs. 2-8c and 2-8d). These results suggest that the *Pp* Pf-5 treatment distinctly influences Fe solubility under the tested conditions, concurrently leading to the decreasing pH and EC of the suspensions.

The effects of *Pp* Pf-5 inoculation on total soluble Fe concentrations, pH, and EC are unlikely to be related to chitinase production since similar trends are observed in both the nano-metaVT and nano-CT-metaVT treatments. Even though both *Pc*O6 and *Pp* Pf-5 produce Pvd, no significant effects on total soluble Fe, pH, and EC are observed with *Pc*O6 treatment, indicating that Pvd is not the primary mechanism by which *Pp* Pf-5 enhances total soluble Fe. Moreover, E-Pch, another siderophore produced by *Pp* Pf-5, has a significantly lower iron-binding affinity ($K_a = 2 \times 10^5 \text{ M}^{-1}$) than Pvd ($K_a = 10^{32} \text{ M}^{-1}$), reflecting its lower Fe chelation capacity.²⁵⁻²⁷ Moreover, the presence of Fe in solution might inhibit the production of bacterial siderophores. This suggests that the mechanisms underlying the effects of *Pp* Pf-5 inoculation may involve complex interactions beyond chelation by the siderophore.

Figure 2-7. Effect of *Pp Pf-5* inoculation on total soluble Fe concentrations in nano-metaVT-SPE (a) and nano-CT-metaVT-SPE (b) suspensions. The impact of *Pp Pf-5* inoculation on total soluble P concentrations in nano-metaVT-SPE (c) and nano-CT-metaVT-SPE (d) suspensions. Error bars represent the standard deviation of the nine replicates. Baseline: The initial total soluble Fe and P concentrations in SPE before adding the treatment.

Figure 2-8. Effect of *Pp* Pf-5 inoculation on pH in nano-metaVT-SPE (a) and nano-CT-metaVT-SPE (b) suspensions. The impact of *Pp* Pf-5 inoculation on EC in nano-metaVT-SPE (c) and nano-CT-metaVT-SPE (d) suspensions. Error bars represent the standard deviation of the nine replicates. Baseline: The initial pH and EC of SPE before adding the treatment.

Inoculation with *Pp* Pf-5 causes a decrease in pH levels in both the nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions compared to the suspensions without microbial presence, which results in higher soluble Fe concentrations. To assess the impact of this pH reduction on solubility, the Visual MINTEQ model was utilized. The pH levels in nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions without *Pp* Pf-5 inoculation are recorded at 7.9 and 7.8 on Day 0, while those with inoculation measured 7.5 and 7.4 after 7 days, respectively (Figures 2-8a and 2-8b). In Figure 2-9b, nano-metaVT-SPE with *Pp* Pf-5 shows a 19.6% increase in total soluble Fe concentration compared to the suspension without microbes, while the model predicts only a 11.1% increase when the pH decreases from 7.9 to 7.5. Similarly, nano-CT-metaVT-SPE with *Pp* Pf-5 inoculation exhibits a 27.3% increase in total soluble Fe concentration compared to the non-inoculated, with a pH reduction from 7.8 to 7.4. However, the predicted increase in total soluble Fe concentration is only 12.0%. The discrepancies between the experimental results and model predictions suggest that the increase in Fe concentrations due to *Pp* Pf-5 inoculation is not solely attributable to the pH decrease. *Pp* Pf-5 may produce other compounds not analyzed in this study that enhance Fe dissolution from both nano-metaVT and nano-CT-metaVT minerals. Conversely, the differences between the experimental and predicted increases in total P concentrations are relatively modest, suggesting that the observed increase in total P concentrations is largely due to the reduction in pH observed in the suspensions.

The findings found that different bacterial strains have varied effects on the solubility of nano-metaVT and nano-CT-metaVT. Furthermore, the interactions observed with *Pp* Pf-5 provide deeper insights into the solubilities of nano-metaVT and nano-CT-

metaVT within SPE suspensions, offering a more realistic approximation of actual soil environmental conditions than results from simpler electrolyte suspensions like KCl. Previous studies have primarily focused on the solubility of vivianite in relatively simple suspension systems such as electrolytes (e.g., CaCl₂) or solutions of LMWOAs, e.g., citric acid, often overlooking the critical role of soil microbes in soil solution chemistry.^{21, 39, 42} Therefore, the mechanisms by which *Pp* Pf-5 enhances the solubilization of nano-metaVT and nano-CT-metaVT than no-microbe treatments in more complex environments warrant further detailed investigation.

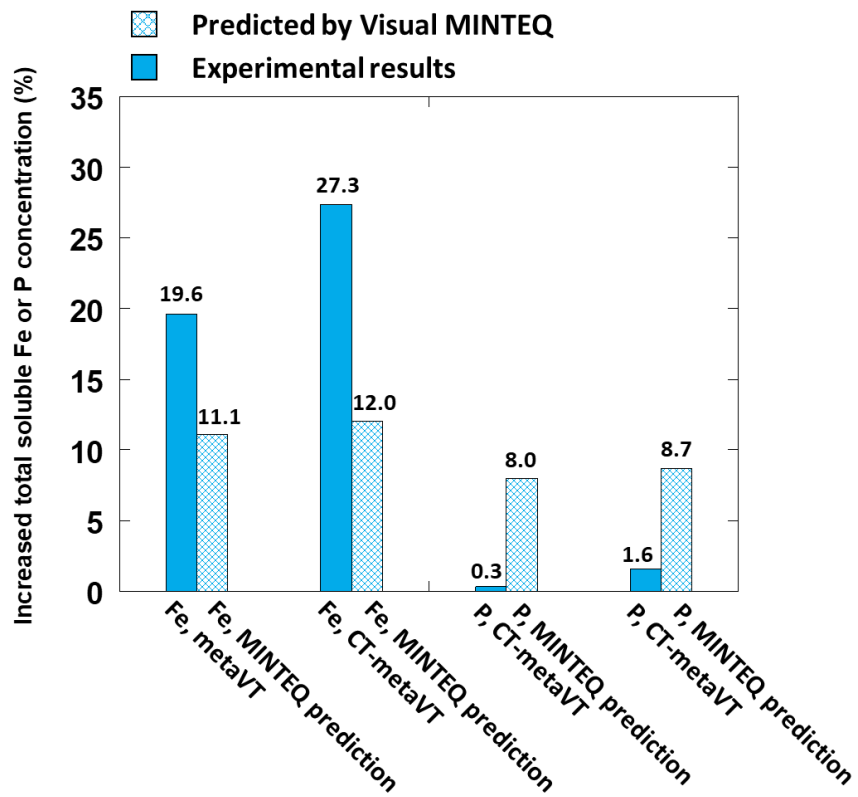

Figure 2-9. The increased total soluble Fe and P concentrations of nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions with *Pp* Pf-5 inoculation are compared to the increased total soluble Fe and P concentrations in vivianite-SPE suspension predicted by Visual MINTEQ.

2.4.2.4 Role of chitosan coating

Fig. 2-9 highlights the impact of the CT coating on nano-metaVT solubility by comparing the total soluble Fe and P concentrations in nano-metaVT- and nano-CT-metaVT-SPE suspensions. Figs. 2-9a and 2-9b demonstrate that nano-CT-metaVT-SPE suspensions consistently display significantly higher total soluble Fe concentrations than those of nano-metaVT-SPE, regardless of the presence of *Pp Pf-5*. Analyses using a generalized linear mixed model indicate higher intercept values for nano-CT-metaVT-SPE suspensions, both without and with *Pp Pf-5* inoculation, at 32.6 and 42.1 respectively. A similar trend is observed for total soluble P concentrations, as depicted in Figs. 2-9c and 2-9d. Specifically, the intercept values for nano-CT-metaVT-SPE suspensions are 616.1 without *Pp Pf-5* inoculation and 655.7 with it, both significantly higher than those recorded for nano-metaVT-SPE. Thus the CT coating enhances the solubilities of both Fe and P in the nano-CT-metaVT in SPE suspension in seven days even though the pH of the nano-CT-metaVT-SPE suspensions are not different from those in nano-metaVT-SPE suspensions, as shown in Figs. 2-10a and 2-10b. Similarly, the EC values are consistent between the two types of materials, as shown in Figs. 2-10c and 2-10d.

CT, being a linear polysaccharide, is typically insoluble under alkaline conditions (pH > 6.0), which raises questions regarding its behavior in the SPE solution (pH 8.4). The purpose of modifying nano-metaVT's surface with CT was to provide an insoluble coating under alkaline conditions and create a positively charged surface that might enhance the retention of nano-CT-metaVT in soil. For example, Ha et al. (2019) showed that CT-encapsulated N, P, and K nano fertilizers increased cucumber yield, suggesting

that the positive charge of chitosan and K might increase stomatal cell osmotic pressure, leading to greater stomatal conductance.⁴³ Similarly, Wu et al. (2008) used CT as a coating on NPK fertilizers to slow their release.¹⁷ CT not only acts as a slow-release layer but also enhances bioavailability in calcareous soils. For instance, CT-encapsulated Zn nanoparticles have been shown to promote maize growth, alleviate Zn deficiency in alkaline soils⁴⁴, and enhance wheat growth in sandy soils.⁴⁵ In this study, however, the CT coating in nano-CT-metaVT does not slow Fe and P release compared to un-coated nano-metaVT but does lead to higher total soluble Fe concentrations in the alkaline SPE.

Figure 2-10. Total soluble Fe concentrations in nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions without (a) and with (b) *Pp* Pf-5 inoculation. Error bars represent the standard deviation of the nine replicates. Baseline: The initial total soluble Fe and P concentrations in SPE before adding the treatment.

Figure 2-11. The pH of nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions changed over time without (a) and with (b) *Pp* Pf-5 inoculation. The EC of nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions changed over time without (c) and with (d) *Pp* Pf-5 inoculation. Error bars represent the standard deviation of the nine replicates. Baseline: The initial pH and EC of SPE before adding the treatment.

2.4.3 Geochemical modeling

LMWOAs exudated by plant roots and bacteria in soils contribute to the enhanced solubility of metals and improved nutrient assimilation. Additionally, AAs secreted into the rhizosphere also influence metal interactions. A SPE contains soluble LMWOAs and AAs in the suspension, which can simulate, though not identically, the chemical reaction with nano-metaVT and nano-CT-metaVT occurring in a soil solution. Naturally occurring soluble organic compounds in soils, such as fulvic acids (FAs), which contain ligand functional groups, are recognized for their capacity to bind to iron within the system. This interaction has a consequential effect on the dissolution rate and bioavailability of iron in the environment.

In Fig. 2-11a, the nano-metaVT-KCl and nano-CT-metaVT-KCl suspensions without microbe inoculation show a total soluble Fe concentration of $1147 \pm 55 \mu\text{g L}^{-1}$ and $654 \pm 92 \mu\text{g L}^{-1}$, respectively, and total soluble P concentration of $630 \pm 16 \mu\text{g L}^{-1}$ and $699 \pm 53 \mu\text{g L}^{-1}$ after seven days, respectively. The empirical results in the nano-metaVT-KCl suspension are lower than the total dissolved Fe concentration ($11,698 \mu\text{g L}^{-1}$) and total dissolved P concentration predicted ($4107 \mu\text{g L}^{-1}$) by the Visual MINTEQ speciation model (Fig. 2-12a). Similarly, the nano-CT-metaVT-KCl suspensions resulted in lower than predicted total dissolved Fe concentration, $5,202 \mu\text{g L}^{-1}$, and predicted total dissolved P concentration, $1,910 \mu\text{g L}^{-1}$.

In Fig. 2-11b, the total soluble Fe concentration of nano-metaVT-SPE and nano-CT-metaVT-SPE suspensions with *Pp Pf-5* inoculation are higher than in the suspensions without microbes. However, the measured total soluble Fe concentrations in the suspensions are about 28-38-fold lower than the concentrations predicted by the

MINTEQ model. The total soluble P concentrations in the nano-CT-metaVT-SPE suspensions are higher overall than in the nano-metaVT-SPE suspensions. Thus, the experimental results of total soluble P concentrations in SPE suspensions are closer to the total dissolved P concentrations predicted by the MINTEQ model, compared to total soluble Fe concentrations. The results suggested that incongruent dissolution of nano-metaVT and nano-CT-metaVT occurs in SPE suspension.

Overall, the total soluble Fe concentrations in both the nano-metaVT and nano-CT-metaVT suspensions in either KCl or SPE are significantly lower than the Visual MINTEQ prediction values. However, there are limitations to the visual MINTEQ model, which must be taken into account. First, thermodynamic constants are only available for pure vivianite in which all the Fe is present as Fe^{II} , unlike the mixed redox state of nano-metaVT. At a given pH, Fe^{III} is less soluble than Fe^{II} , suggesting that metaVT (more oxidized than VT) is likely less soluble than pure VT. The thermodynamic constant of nano-metaVT, a partially oxidized form of vivianite, is undefined and understudied due to the complexity arising from its various possible oxidation states. Another significant limitation is the modeling of reaction time. Visual MINTEQ predicts outcomes based on fully completed reactions, but in reality, nano-metaVT and nano-CT-metaVT in this study only have seven days for weathering.

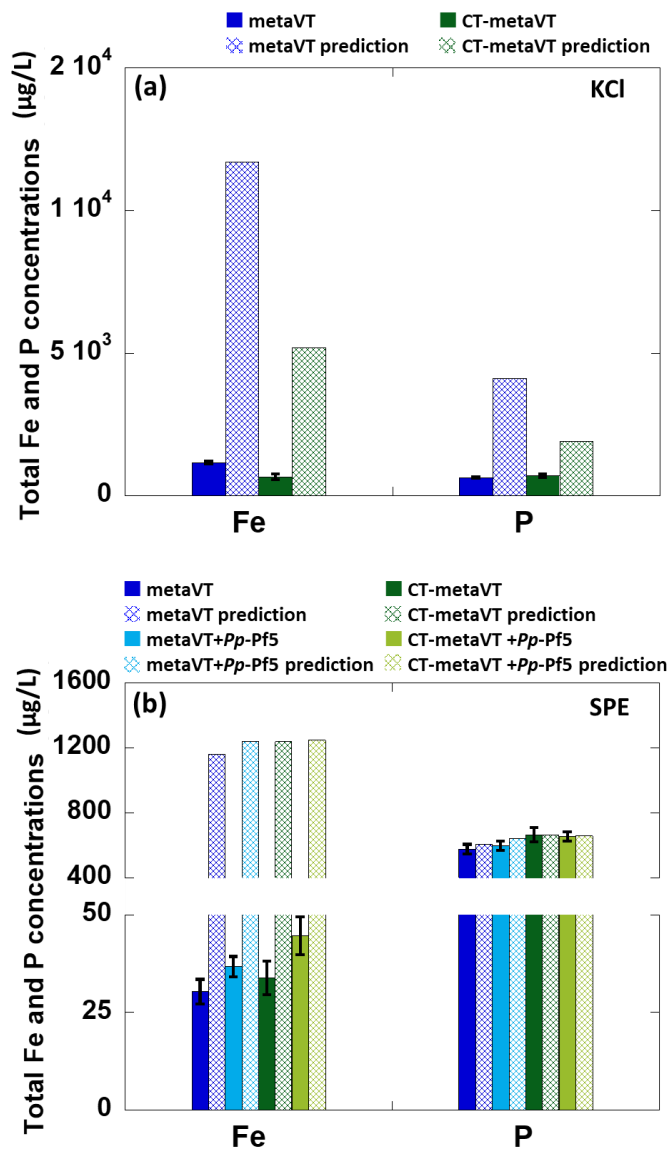

Figure 2-12. The total Fe and P concentrations in nano-metaVT-KCl and nano-CT-metaVT-KCl suspensions after seven days (a). The solid color bars represent experimental results, and the dotted yellow lines represent the Visual MINTEQ predicted values. The total Fe and P concentrations in nano-metaVT-SPE and nano-CT-metaVT-SPE after seven days (b), including the microbial inoculation treatments. The solid color bars represent experimental results, and the pattern-filled bars represent the values predicted by Visual MINTEQ.

Schütze et al. (2020) compared the P release rate from vivianite in CaCl_2 and citric acid solutions ($0.01\text{--}0.1 \text{ mol L}^{-1}$, pH 6) in seven days.³⁹ The results showed that the released P concentrations in citric acid are 320-466-fold higher than in CaCl_2 solution, indicating the critical role of LMWOAs in the solubility of phosphate minerals. Similar results were shown in a Gypser and Freese (2020) study, reporting that the concentrations of P release from vivianite in various solutions after 1,344 h follow the order: citric acid (83.9%) > humic acid (8.1%) > CaSO_4 (1.7%) > CaCl_2 (1.4%).²¹ The release of P bound by organic acids includes the processes of mineral dissolution, direct ligand exchange, and the replacement of P by organic acid anions, the formation of metal–organic complexes, and the blocking of P adsorption sites.^{20, 46} We did not detect citric acid in the SPE, which might be due to its rapid consumption by soil microbes during SPE preparation process. The complete secondary metabolite analyses, including siderophores secreted by soil organisms, are difficult to quantify based on the current technology. Still, they play an important role in the solubility of Fe-minerals. There are other compounds reacting with Fe from nano-metaVT and nano-CT-metaVT in this system. From Table 2-8, it is clear that 99.98% Fe^{3+} and 82.24% Fe^{2+} are bound by FA and that there are 54.93% HPO_4^{-2} and 20.38% CaHPO_4 in the nano-vivianite-SPE suspensions, as predicted by visual MINTEQ. The results indicate that FA is the predominant ligand complexing Fe in the SPE suspensions.

Table 2-7. The Fe and P speciation in metaVT-SPE and CT-metaVT-SPE suspensions predicted by visual MINTEQ.

Component	Species name	metaVT-SPE	CT-metaVT-SPE
		% of total concentration	
Fe ³⁺	FA2-Fe ^{III} (7)(aq)	100	100

2.5 Conclusions

In this study, we investigated the solubilities of nano-metaVT and nano-CT-metaVT in a simple electrolyte solution ($0.003 \text{ mol L}^{-1} \text{ KCl}$) and in a calcareous SPE, which contains LMWOAs, amino acid, fulvic acid, and humic acid, and a solid surface. In KCl solution, the total soluble Fe concentration of nano-CT-metaVT suspensions is significantly lower than that of nano-metaVT suspensions after 7 days, which might be due to the insoluble CT coating limiting the solubilization of nano-CT-metaVT. Conversely, the nano-CT-metaVT resulted in significantly higher total Fe concentrations than nano-metaVT in SPE after 7 days. This result suggests that the CT coating effectively increases Fe solubility. On the other hand, *Pp Pf-5*, a beneficial soil microbe, significantly influences the solubilities of both nano-metaVT and nano-CT-metaVT, increasing the total soluble Fe concentration in SPE suspensions by not only lowering the environmental pH but also involving other mechanisms, which remains unclear. The total soluble P concentrations of both nano-metaVT and nano-CT-metaVT in a KCl solution are found to be 152-160 times higher than bulk vivianite in a CaCl_2 solution, as reported in the previous study, suggesting a significant impact of particle size on solubility. Even though the total soluble Fe concentration of nano-metaVT and nano-CT-metaVT in the SPE suspensions (pH 8.4) are still much lower than in the KCl suspensions (pH 5.9), our findings highlight the key factors that affect the solubilities of nano-metaVT and nano-CT-metaVT, including functional coating on the nano-fertilizers and the presence of soil microbes, LMWOAs, and AAs. Future research could explore the mechanisms behind the interactions between the nano-metaVT and nano-CT-metaVT, potentially leading to more refined and efficient alternative Fe amendments.

CHAPTER 3

***Pseudomonas protegens* Pf-5 mitigate salinity stress in wheat grown with nano-metavivianite and nano-chitosan-coated metavivianite as Fe amendments**

3.1 Abstract

In arid and semi-arid regions, soil salinity and iron (Fe) deficiency significantly hinder agricultural productivity. Fe, essential for plant and microbial growth, is often applied in agriculture as soluble chelated Fe, which is prone to leaching in high-pH calcareous soils. This study explores the use of nano-sized metavivianite ($\text{Fe}^{\text{II}}\text{Fe}_2^{\text{III}}(\text{PO}_4)_2(\text{OH})_2 \cdot 6\text{H}_2\text{O}$; metaVT) as an alternative Fe amendment. In an attempt to optimize the efficacy of the amendment, we employed chitosan (CT), recognized for its biocompatibility and non-toxicity, as a positively charged coating for nano-metaVT. In a modified half-strength Hoagland solution ($1/2\text{HS}$), the culturability of *Pseudomonas protegens* Pf-5 (*Pp* Pf-5) improved with Fe-EDDHA and nano-metaVT addition and even more so under saline conditions with nano-metaVT. Wheat was grown in sand with $1/2\text{HS}$ and supplemented with *Pp* Pf-5 to model nutrient competition and growth enhancement by the soil microbe. The salinity stress ($\text{EC} = 10 \text{ dS} \cdot \text{m}^{-1}$; $\text{pH} = 8.4$) was imposed by added sodium (Na) and calcium (Ca) salts. The results show that nano-CT-metaVT and Fe-EDDHA-treated wheat have longer shoot lengths than the controls. Wheat inoculated with *Pp* Pf-5 exhibits approximately 2.3 to 2.9 times higher transpiration rates than wheat grown without microbial inoculation. This elevated transpiration rate suggests mitigation of salinity stress with microbial colonization of the wheat plants. However, Fe additions do not have any effect despite wheat root colonization and nano-CT-metaVT particle's presence on the roots, as confirmed via EDS analyses. While the various iron sources had

minimal impacts on wheat growth over the 14-day study, the findings highlight the potential of *Pp* Pf-5 inoculation as a strategy to mitigate salinity stress in wheat, warranting further investigation in future studies.

Keywords: chitosan coating, iron deficiency, metavivianite, *Pseudomonas protegens* Pf-5, salinity stress, wheat

3.2 Introduction

Soil salinity is a global issue because of its negative impact on agricultural production, especially in arid and semi-arid areas. More than 20% of soils worldwide are salt-affected, with levels continuously increasing owing to anthropogenic activities and climate change (Jesus et al., 2015; Okur and Örgen, 2020). Excess salt accumulation obstructs the growth of crops by limiting their ability to take up water, resulting in an ion imbalance (Abdoli et al., 2020). An adequate iron (Fe) supply is beneficial for plants experiencing salinity stress (Rabhi et al., 2007). For example, Mozafari et al. (2018) showed that the application of Fe nanoparticles (0.8 ppm) to grapes (*Vitis vinifera* L. cv. Merlot' Khoshnaw') growing under salinity stress increased their contents of free proline and total protein as well as their enzymatic antioxidant activity.

In arid and semi-arid regions, Fe deficiency is a common problem (Abadia et al., 2011). Carbonate-rich soils in the semi-arid Western U.S. have characteristics rarely found in humid regions (Weil and Brady, 2017). Calcium carbonate accumulation often occurs in these soils, forming calcic horizon in the soil profile (Durand et al., 2018). In addition, the cations released by mineral weathering accumulate instead of leaching out of the profile because of the low precipitation and high evapotranspiration. Therefore, the

pH values of soils in arid and semi-arid environments are generally 7 or above. Inorganic Fe is quickly rendered unavailable due to the rapid formation of iron hydroxides in a pH_{saturated paste extract} 8 soil, the free Fe³⁺ concentration is around 10^{-21.3} M, and the total soluble Fe is around 10^{-10.2} M (Kim and Guerinot, 2007). Microbes require total soluble Fe concentrations of 10⁻⁷–10⁻⁵ M, and plants require 10⁻⁹–10⁻⁴ M in the soil solution for optimal growth (Lemanceau et al., 2009; Schenkeveld, 2010), which is approximately 10¹–10⁶ higher than the total soluble Fe concentration in alkaline soil solution. Fe participates in essential metabolic processes (Brittenham, 1994; Kobayashi and Nishizawa, 2012; Morrissey and Guerinot, 2009). Plants and microbes acquire Fe via different strategies, such as the production of siderophores or through rhizosphere acidification. Conventional amendment with synthetic Fe-chelates is commonly used to prevent Fe deficiencies in calcareous soils (Rajaie and Tavakoly, 2018). However, within one day of application, a decline in Fe concentration was found in soil solutions treated with Fe-EDDHA, and one of the Fe-EDDHA components, *o,p*-Fe-EDDHA, revealed the tendency to exchange Fe for Cu (Schenkeveld et al., 2012). The high solubility of Fe-chelates also implies potentially high-risk mobilization and subsequent leaching of metals into groundwater. Therefore, researchers are still looking for natural, high-purity, slow-release Fe fertilizers that are environmentally friendly (Abadia et al., 2011).

Vivianite (Fe^{II})₃(PO₄)₂·8H₂O; VT) is an Fe phosphate mineral that usually occurs in reduced sediments. The partially oxidized form of vivianite, metavivianite (Fe^{II}Fe^{III})₂(PO₄)₂(OH)₂·6H₂O; metaVT), is more common in an aerobic environment where it remains stable for extended periods of time (Rouzies and Millet, 1993). MetaVT can also be recovered from secondary sewage effluent, which often has a high

phosphorus content (Feigin et al., 1991; Jowett et al., 2018). Lin et al. (2017) demonstrated that 31% of the phosphorus in sludge can be recovered as vivianite through a chemically enhanced primary sedimentation process. MetaVT has shown the potential to provide Fe in calcareous soil (Ammari and Hattar, 2011; Bavaresco et al., 2010; Diaz et al., 2010).

Current agricultural production relies on chemical fertilizers to fulfill the growing demand for food (Zhang et al., 2015), however, low nutrient use efficiency and over-application of chemical fertilizers compromise soil health (Fess et al., 2011). Therefore, there is great interest in applying nano fertilizers to increase fertilizer use efficiency, lower applied fertilizer doses, and minimize volatilization and leaching (Seleiman et al., 2021). With a high surface area to volume ratio, nano-sized particles exhibit properties distinct from conventional bulk fertilizers. Thus, the application of nano fertilizer has the potential to promote sustainability in agriculture. Additional attempts to improve the efficiency of Fe amendments in soils focus on modifying the nano-fertilizer surface. Nano fertilizers modified by polymer coatings can slow down the release of nutrients, improve fertilizer utilization, and reduce leaching losses of fertilizers (An et al., 2022). Our goal is to maximize interaction between plant roots and the nano-fertilizer in the rhizosphere and minimize losses due to sorption to soil particle surfaces or leaching. Since nano-metaVT has a negative surface charge, we investigated positively-charged chitosan (CT), the N-deacetylated derivative of chitin, as a possible surface coating. CT was selected based on its biodegrading ability, low cost, non-toxic properties (Mikula et al., 2020), and insolubility under alkaline conditions ($> \text{pH } 6$). CT was used as a surface coating material for nano-metaVT in this study. Both nano-metaVT and nano-CT-

metaVT prepared in this study have one dimension in the nano-size range, and their effectiveness was evaluated and compared to a conventional Fe-chelate, Fe-EDDHA, in a sand culture pot system.

Many rhizobacteria promote plant growth and protect the plant from abiotic stresses by providing access to nutrients otherwise unavailable to roots (Backer et al., 2018; Singh et al., 2018). In return, these symbiotic bacteria receive photosynthetically derived carbon in the form of sugars, amino acids, and organic acids from plant root exudates (Anderson et al., 2023; Canarini et al., 2019; Shinde et al., 2017). *Pseudomonas protegens* is a gram-negative, soil-dwelling bacterium with biological control activity (Balthazar et al., 2022; Ruiu and Mura, 2021). *Pseudomonas protegens* (*Pp* Pf-5) produces several types of siderophores for Fe chelation, including pyoverdines (Pvds) and enantio-pyochelin (E-Pch) (Drehe et al., 2018). Previous studies have shown the potential of *Pp* Pf-5 to promote the growth of plants by producing siderophores and enzymes that can inactivate pathogens (Ruiu and Mura, 2021). Additionally, there is an overexpression of certain genes and proteins associated with the synthesis of secondary metabolites under Fe-limited conditions. *Pp* Pf-5 is also reported to produce chitinase which can degrade fungal cell walls and cause the cell lysis of fungal pathogens (Lim et al., 2012). However, understanding the effect of salinity stress on *Pp* Pf-5 and plants supplied with various sources of Fe remains unclear.

This study investigates the effect of *Pp* Pf-5 inoculation on wheat grown in a sand matrix amended with nano-metaVT, nano-CT-metaVT, or commercial Fe-EDDHA. A gnotobiotic growing system using silica sand as the growth matrix was used in this experiment to avoid the complexity of working with intact soils. The pH of the modified

(Fe-deficient) half-strength Hoagland solution was adjusted to pH 8.4 to simulate the pH value in calcareous soil. Salinity stress ($EC = 10 \text{ dS}\cdot\text{m}^{-1}$) was also applied to the wheat system to explore the interaction between *Pp Pf-5* and wheat under abiotic stress with the presence of different Fe sources. We hypothesize that Fe amendment benefits *Pp Pf-5* in $\frac{1}{2}$ HS suspensions under salinity stress. Moreover, compared to the negative control, nano-metaVT and nano-CT-metaVT improve Fe uptake and mitigate the salinity stress in wheat grown for 14 days. Finally, *Pp Pf-5* improves Fe uptake and mitigates the salinity stress, compared to control, in wheat grown for 14 days. Our study provides insight into the effectiveness of nano-metaVT and nano-CT-metaVT for Fe supply and the effects of root colonization by *Pp Pf-5* on wheat growth under salinity stress.

3.3 Materials and Methods

3.3.1 Bacterial culturability with various Fe sources under salinity stress

To evaluate the effects of Fe and salinity on culturable *Pp Pf-5* (CFU mL^{-1}) in modified half-strength Hoagland solution ($\frac{1}{2}$ HS), treatments with triplicates were conducted in sterile polypropylene 250-mL bottles in a 4×2 factorial design with eight treatments. The treatments were unamended controls; the presence/absence of the Fe sources, including nano-metaVT, nano-CT-metaVT, and Fe-EDDHA, at $33.3 \text{ mg Fe L}^{-1}$; and the presence/absence of salinity stress. The growth broth was $\frac{1}{2}$ HS with 1 g L^{-1} sucrose added as a carbon source. The initial bacterial concentration of *Pp Pf-5* was $1.0 \times 10^6 \text{ CFU mL}^{-1}$. The cultures were shaken at 100 rpm in the dark throughout the reaction. Aliquots were removed at 0 and 72 h, and culturable cells were determined by plating serial dilutions onto tryptic soy agar (TSA) plates to determine the bacterial CFU mL^{-1} .

Sterilized double-deionized water (resistance > 18 M Ω cm) was used to prepare a $\frac{1}{2}$ HS solution. The $\frac{1}{2}$ HS with the composition reported in Potter et al. (2021) was modified by the omission of ferric chloride (FeCl₃·6H₂O) (Table B3-1) and had a pH of 5.3 and EC of 1.3 dS·m⁻¹ adjusted to pH 8.4 with 0.5 M KOH.

3.3.2 Wheat growth experiment

3.3.2.1 Wheat (*Triticum aestivum*)

Winter wheat (*Triticum aestivum* cv. Juniper) seeds harvested in 2018 were surface-disinfected in fresh 10% H₂O₂ for 15 minutes, then rinsed ten times using sterile double-deionized water. Ten seeds selected at random were placed on LB plates, then sealed with a parafilm and incubated at 23 °C for 48 h to confirm the absence of microbial contaminants. Quartz sand (4075; Unimin Corp; New Canaan, CT, USA) was washed with double-deionized water, then heated at 550 °C in a muffle furnace for 8 h to remove residual organic matter and to sterilize. Then sand matrix, 300 g, was mixed with nano-metaVT, nano-CT-metaVT, or Fe-EDDHA (Sequestrene[™] 138, C₁₈H₁₆FeN₂O₆·Na) at a dose of 5 mg Fe kg⁻¹ and transferred to acid-washed, sterile, magenta boxes (V8505, 10 × 7 × 7 cm, Sigma-Aldrich, St Saint Louis, MO, USA). The treatments with triplicates were conducted in magenta boxes using a 4 × 2 × 2 factorial design with 16 treatments. The treatments were the presence/absence of the Fe sources, nano-metaVT, nano-CT-metaVT, or Fe-EDDHA, each at 5 mg Fe kg⁻¹; the presence/absence of *Pp* Pf-5; and the presence/absence of salinity stress. The effectiveness of nano-metaVT and nano-CT-metaVT is expected to be better than that of the positive control (without Fe) and comparable to that of the positive control, Fe-EDDHA.

3.3.2.2 Growth conditions and the salinity stress treatment

In this study, salinity stress was induced by adding NaCl and CaCl₂, at a molar concentration ratio of 2:1, to the ½HS (pH 8.4), achieving EC values of 10 dS·m⁻¹. This specific salinity level, 10 dS·m⁻¹, was selected based on preliminary experiments identifying it as a concentration that significantly impairs Juniper wheat growth. The saline ½HS contained 42 mM NaCl and 21 mM CaCl₂. Each growth box was filled with 45 mL sterilized, ½HS (EC = 1.3 dS·m⁻¹) or saline ½HS (EC = 10 dS·m⁻¹) to achieve 150% of its field capacity (0.15 g H₂O g⁻¹ sand). Field capacity was measured with a soil tensiometer. The matrix is considered to be at field capacity when the water potential in the sand is at -33 kPa. Ten surface-sterilized seeds were placed in the sand matrix at an approximate depth of 5 mm and lightly covered with sand. The treatments with the added soil microbe, *Pp* Pf-5, were inoculated by injecting 0.45 mL aliquots of a 2 × 10⁶ CFU mL⁻¹ bacterial suspension into the box, making an initial bacterial concentration in each magenta box of about 2.0 × 10⁴ CFU mL⁻¹.

Wheat was grown for 14 d in an environmental growth chamber at 25 ± 2 °C, under high-energy sodium lights (Yescom USA Inc., City of Industry, CA, USA) and fluorescent lamps (F54W/T5/841/ECO, GE 46761) with 16/8 h light/dark photocycle periods. The light panels were fixed at approximately 70 cm above the base of the pots with an average photon flux of 350 μmol⁻¹ m⁻² s⁻¹. After growing for 9 d, the lids of the magenta boxes were removed when the shoot tips were about to hit the top of the boxes. Plants were watered daily with sterile double-deionized water to replace water lost through evapotranspiration gravimetrically. The masses of the magenta boxes were recorded every day after removing the lid to calculate the water lost from evaporation

(W_E) and plant transpiration (W_T). Another set of experiments was conducted with the same condition, but with no plants growing in the magenta boxes to calculate the water loss from the nonplanted growth matrix via evaporation (W_E), then the water loss from plant transpiration (W_T) was estimated as:

$$W_T = W_{Total} - W_E$$

where W_{Total} represents the total water loss (g) in the magenta boxes with wheat growing; W_E represents the average of water loss via evaporation (g) in the magenta boxes without wheat growing.

3.3.2.3 Harvesting methods and determination of growth attributes

At day 14 after seed planting, sterile deionized water was added to each Magenta box to bring the sand water content to 300% of sand field capacity and allowed to equilibrate for 15 minutes. This process resulted in a total of 90 mL of solution in each box, ensuring a sufficient volume of sand pore water for subsequent analyses. The shoot tissue was cut above the coleoptiles, and the shoot length and the fresh mass were measured. The roots were carefully removed from the sand, and root-adhering sand was returned to the sand retained in the box. After uprooting the wheat root tissue from the growth box, the sand pore water of the sand with *Pp* Pf-5 inoculated treatments was extracted and was serially diluted and cultured on the TSA medium. The root tissue was rinsed with sterilized deionized water and placed on tissue paper to absorb the excess water before measuring the root length and root fresh mass. The shoot and root tissues were oven-dried at 60 °C for at least 48 h before the determination of the dry mass.

3.3.3 Elemental analysis of plant tissue

To analyze root and shoot tissue for Fe and P concentrations, the dried plant tissue was weighed (about 0.2 g) and digested with nitric and perchloric acids based on the method described by Zasoski and Burau (1977). The samples were filtered through a 25 mm nylon syringe filter with a 0.22 μm pore size (Thermo Scientific, Waltham, MA, USA) and stored in scintillation vials. The Fe, P, Na, and K concentrations in the digested solution were determined by an inductively coupled plasma mass spectrometer (Agilent 7700x Agilent technologies, Santa Clara, CA, USA).

3.3.4 Root tissue observation via SEM and EDS

The wheat root with *Pp* Pf-5 inoculated treatments was further observed by scanning electron microscopy (SEM, Quanta FEG 650, Field Electron and Ion Company, Hillsboro, OR, USA) and energy dispersive X-ray spectroscopy (EDS, Oxford Instruments, Abingdon-on-Thames, UK) for microbe colonization. The root tissue was prepared following the protocol described by Neinhuis and Edelmann (1996) and observed by SEM. Briefly, root sections from the fine root were immersed in 100% dry methanol for 10 minutes, followed by 100% dry ethanol for 30 minutes, and then transferred to a fresh ethanol solution for 30 min. The samples were critical-point-dried with ethanol as the transitional fluid before being sputter-coated with a 10-nm layer of gold and palladium using a rotary sputter coater system EMS150R ES (Electron Microscopy Sciences, Hatfield, PA). The coated samples were viewed in a SEM under a high vacuum at an accelerating voltage of 20 kV. The nano-metaVT and nano-CT-metaVT particles on the root surface with and without salinity stress were analyzed for elemental composition via EDS using an X-Max detector.

3.3.5 Data analysis

The experimental design for the wheat growth study was structured according to a randomized complete block design (RCBD) with three trials (blocks) per treatment. Three trials (blocks) were conducted, resulting in nine experimental units ($n = 9$) per treatment. This design allowed for the control of variability within the experimental blocks. Plant growth parameters, physiological measurements, and elemental analyses were subjected to statistical evaluation using a three-way Analysis of Variance (ANOVA) performed with SAS software (SAS[®] Studio, release 3.81, Enterprise Edition, Madison, WI, USA). Diagnostics of residuals did not reveal a departure from normality and nonconstant variances, except for the shoot and root sodium (Na) concentrations. Shoot and root sodium (Na) concentrations were log-converted before the data analysis. The adjusted Tukey-Kramer multiple comparison procedure was employed to discern significant differences between treatment means, with a significance level set at 0.05.

For the bacterial culturability experiment, a completely randomized design (CRD) was implemented with three replications ($n = 3$). The bacterial concentration data obtained were log-transformed and statistically analyzed using two-way ANOVA with SAS software (SAS[®] Studio). Significant differences among treatment means were determined using the adjusted Tukey-Kramer multiple comparison procedure, with the level of significance maintained at $\alpha \leq 0.05$.

3.4 Results and Discussions

3.4.1 Bacterial culturability with various Fe sources

Previous results show that *Pp* Pf-5 inoculation increased the total soluble Fe in the nano-metaVT-soil saturated paste extract (SPE) and nano-CT-metaVT-SPE compared with wheat grown without *Pp* Pf-5 (section 2.4.2.3). Fig. 3-1 shows the *Pp* Pf-5 culturability results of shaken liquid culture studies investigating the effect of Fe sources on the growth of *Pp* Pf-5 in ½HS with sucrose as a carbon source. Overall, the higher bacterial culturability at 72 h, about 10–100 times than culturability at 0 h, can be observed with the absence of salinity stress ($EC = 1.3 \text{ dS}\cdot\text{m}^{-1}$) (Fig. 3-1a). Significantly, higher culturable cell numbers occur in the presence of nano-metaVT, 7.9-log CFU mL⁻¹, and to a greater extent Fe-EDDHA, 8.3-log CFU mL⁻¹, but the addition of nano-CT-metaVT failed to boost growth. In Fig. 3-1b, the bacterial culturability of the control treatments drops from 6.0-log to 5.3-log CFU mL⁻¹ at 72 h under salinity stress ($EC = 10 \text{ dS}\cdot\text{m}^{-1}$), while Fe treatments have a significantly higher bacterial culturability of about 7-log CFU mL⁻¹, regardless the type of Fe sources. This finding is consistent with the essential role of Fe in bacterial metabolism. The positive effect of nano-metaVT and Fe-EDDHA on the soil bacterium culturability in suspension might also extend to the soil environment, but this has yet to be determined.

Fig. 3-1. Bacterial culturability of *Pp* Pf-5 with various Fe sources with a dose of 33.3 mg Fe L⁻¹ without salinity stress (EC = 1.3 dS·m⁻¹) (a), and under salinity stress (EC = 10 dS·m⁻¹) (b). A two-way ANOVA was performed. Different letters above the columns represent significant differences based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated from the statistical model.

3.4.2 Effect of *Pp* Pf-5 inoculation on wheat with the presence of different Fe sources

Salinity stress adversely impacts plant growth through mechanisms such as the accumulation of Na^+ in plant tissues, leading to nutrient imbalances and affecting critical physiological processes, such as transpiration (Harris et al., 2010; Pour-Aboughadareh et al., 2021; Saqib et al., 2013). Fig. 3-2 depicts the effects of various Fe sources, salinity levels, and the presence of *Pp* Pf-5 on the wheat growth. Fig. 3-2a shows that the shoot length of the wheat is affected by the different Fe sources, salinity stress, and *Pp* Pf-5 inoculation, but there is no interaction between the three factors. Both the nano CT-metaVT and Fe-EDDHA treatments have longer shoot lengths than the negative control; *Pp* Pf-5 inoculated wheat has longer shoot lengths than the no-microbe treatment. Moreover, the Fe-EDDHA treatment exhibits greater shoot dry mass than the negative control (Fig. 3-2b) but not the nano-metaVT and nano-CT-metaVT treatments. Similarly, there is no significant difference in shoot dry mass between *Pp* Pf-5 inoculation and the no-microbe treatments.

Wheat under salinity stress transpired less than wheat grown without salinity stress across all the Fe treatments. Interestingly, wheat inoculated with *Pp* Pf-5 exhibits approximately 2.3 to 2.9 times higher transpiration rates than wheat grown without microbial inoculation. However, Fe additions do not have any effect (Fig. 3-2c). This elevated transpiration rate suggests mitigation of salinity stress with microbial colonization of the wheat plants. Previous research by Harris et al. (2010) reported that salinity at an EC of $15 \text{ dS}\cdot\text{m}^{-1}$ resulted in a lower grain yield in wheat, primarily due to the reduced biomass associated with decreased transpiration. In contrast, the current

study's observation of higher transpiration and increased shoot length in *Pp* Pf-5 inoculated wheat suggests a mitigating effect on the salinity stress.

Research on other *P. protegens* isolates, SN15-2 and CHA0, suggests multiple adaptive strategies to hyperosmotic conditions, including cytoplasmic K⁺ accumulation, compatible solute synthesis, Na⁺ ion exclusion, and membrane alteration (Wang et al., 2020). The isolate *P. protegens* CHA0 also significantly improves the growth of pea and its salinity tolerance under hydroponic conditions (Patel et al., 2023). Despite extensive research on the anti-pathogen ability of *Pp* Pf-5 (Rathore et al., 2020; Sexton et al., 2017), anti-fungal (Balthazar et al., 2022), and bio-control (Loper et al., 2016; Ruiu and Mura, 2021) properties, studies specifically investigating *Pp* Pf-5's salt tolerance are limited (see Table 3-1). It is promising to explore further the mechanisms that *Pp* Pf-5 contributes to reduced Na uptake in wheat shoot tissues, thereby alleviating salt stress.

Fig. 3-2. Shoot length (a), dry mass (b), and plant transpiration (c) of wheat grown in the sand with the four Fe treatments (control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA). A three-way ANOVA was performed. Different letters above columns represent significant differences based on the Tukey test ($\alpha \leq 0.05$). Error bars represent the standard error calculated from the statistical mix model.

Table 3-1. Summarization of recent studies related to *Pseudomonas protegens*.

Microbe	Bacterial concentration	Target	Performance	References
<i>Improve the plant growth</i>				
<i>Pseudomonas protegens</i> Pf-5	10 ⁴ CFU ml ⁻¹	Wheat (<i>Triticum aestivum</i> v. Juniper, winter wheat)	Wheat grown in the sand at pH 8.4 and inoculated with <i>Pp</i> Pf-5 showed the potential to mitigate the salinity stress (42 mM NaCl and 21 mM CaCl ₂) by increasing the plant transpiration (see section 3.4.1).	This study
<i>Pseudomonas protegens</i> CHA0	2.4 × 10 ⁸ CFU ml ⁻¹	Pea (<i>Pisum sativum</i>)	<i>Pp</i> CHA0 greatly improved the growth and tolerance against salinity of pea plants grown in hydroponic conditions.	(Patel et al., 2023)
<i>Pseudomonas protegens</i> Pf-5	NA	Cumin (<i>Cuminum cyminum</i> L)	<i>Pp</i> Pf-5 exhibited the highest <i>in vitro</i> growth inhibition (82 %) against <i>Fusarium oxysporum</i> f. sp. <i>cumini</i> (<i>Foc</i>), the causal pathogen of cumin wilt. <i>Pp</i> Pf-5 produced high protease and chitinase activities. <i>Pp</i> Pf-5 antagonism of <i>Foc</i> growth correlated with decreased production of cellulase and polygalacturonase, enzymes important in plant cell wall degradation.	(Rathore et al., 2020)
<i>Pseudomonas protegens</i> Pf-5	4 × 10 ⁹ CFU ml ⁻¹	Aspen seeds (<i>Populus tremuloides</i> Michx.)	<i>Pp</i> Pf-5 colonization increased root length (2.3-fold) and root mass (4.5-fold) under low P compared to growth without microbial inoculation.	(Shinde et al., 2017)
<i>Bio-control for pathogens</i>				
<i>Pseudomonas protegens</i> Pf-5	10 ⁵ CFU ml ⁻¹	Cannabis crops (<i>Cannabis sativa</i> L.)	<i>Pp</i> Pf-5 has biocontrol activity against cannabis fungal pathogens, including <i>Botrytis cinerea</i> .	(Balthazar et al., 2022)
<i>Pseudomonas protegens</i> Pf-5	NA	<i>Pseudomonas aeruginosa</i> PAO1	The success of <i>Pp</i> Pf-5 against inter-species competitor <i>P. aeruginosa</i> PAO1 was contingent on its production of a pyoverdine siderophore for Fe chelation.	(Sexton et al., 2017)
<i>Pseudomonas protegens</i> Pf-5	NA	genus <i>Fusarium</i>	Secretion of the siderophore pyoverdine was observed when <i>Pp</i> Pf-5 was grown in the presence of fusaric acid. Fe sequestration partly accounts for the resistant mechanism against the mycotoxin in <i>Pp</i> Pf-5.	(Ruiz et al., 2015)

<i>Bio-control for insects</i>				
<i>Pseudomonas protegens</i> Pf-5	10 ⁸ CFU ml ⁻¹	<i>Musca domestica</i> and <i>Lucilia caesar</i> larvae	<i>Pp</i> Pf-5 caused 100% mortality toward <i>Musca domestica</i> and <i>Lucilia Caesar</i> .	(Ruiu and Mura, 2021)
<i>Pseudomonas protegens</i> Pf-5	NA	<i>Drosophila melanogaster</i>	Extracellular chitinase, the secretion of rhizoxin analogs, and orfamide A contribute to this oral toxicity of <i>Pp</i> Pf-5 to the common fruit fly, <i>D. melanogaster</i> .	(Loper et al., 2016)
<i>Pseudomonas protegens</i> bacterium studies				
<i>Pseudomonas protegens</i> SN15-2	NA	NA	Results indicated <i>P. protegens</i> SN15-2 utilizes multiple strategies for adaptation to hyperosmotic growth environments (450 mM NaCl), including (i) accumulating high cytoplasmic concentrations of K ⁺ , (ii) accumulating low molecular mass compatible solutes, (iii) exclusion of excess Na ⁺ ion in cells, (iv) altering membrane composition.	(Wang et al., 2020)
<i>Pseudomonas protegens</i> Pf-5	NA	NA	Biosynthesis of secondary metabolites with biocontrol activity. 2,4-diacetylphloroglucinol (DAPG), or famine A and pyrrolnitrin, as well as a chitinase, were over-expressed under the Fe-limited condition.	(Lim et al., 2012)

3.4.3 Elemental analysis of plant tissue

Elemental analysis of wheat shoot tissues, both under normal and salinity stress conditions, shows that growth with Fe-EDDHA consistently results in significantly higher Fe concentrations in the shoot tissues compared to the control, with or without *Pp* Pf-5 inoculation (Fig. 3-3a). Interestingly, such an increase in Fe concentration is not observed in the wheat shoots treated with nano-metaVT and nano-CT-metaVT over the 14-day growth period. This could be attributed to the nature of nano-metaVT and nano-CT-metaVT as mineral forms of Fe that require weathering or dissolution before plant uptake, suggesting the 14 d period in the sand growth matrix may have been insufficient to observe notable differences in shoot Fe content. Regarding Na uptake, significantly higher levels than nano-metaVT and nano-CT-metaVT were detected in the Fe-EDDHA treatment combined with *Pp* Pf-5 inoculation (Fig. 3-3b) at EC of $1.3 \text{ dS}\cdot\text{m}^{-1}$. This might be due to the presence of Na in the Fe-EDDHA (Sequestrene 138, $\text{C}_{18}\text{H}_{16}\text{FeN}_2\text{O}_6\cdot\text{Na}$).

Fig. 3-3c presents the elemental analysis of wheat root tissues grown under both non-saline and saline conditions and with and without *Pp* Pf-5 inoculation. At low EC, wheat treated with Fe-EDDHA exhibits significantly higher concentrations of Fe in root tissues compared to the control, regardless of *Pp* Pf-5 inoculation. However, under salinity stress, Fe concentrations in root tissues are not notably influenced by either the Fe amendments or the presence of *Pp* Pf-5, as compared to the control. This observation parallels the findings in shoot tissues (Fig. 3-2a), where increases in Fe concentrations with nano-metaVT and nano-CT-metaVT treatments were not detected over the 14-day growth period. This lack of increase could be attributed to the slow weathering or dissolution of the nano-metaVT and nano-CT-metaVT amendments within this relatively

short timeframe. According to the Utah Fertilizer Guide, the critical nutrient concentrations for wheat at the early boot stage are 0.15-0.20% P and 1.5-2.0% K on a dry weight basis, with foliar tissue requiring 50-60 mg Fe kg⁻¹ dry weight basis. Elemental analysis of wheat shoot tissues, as shown in Fig. 3-3a (Fe), and appendix Figs. B3-5a (P), and B3-6a (K), indicate that the wheat plants maintained adequate levels of Fe, P, and K at this stage. This sufficiency indicates that Fe deficiency was not evident in the negative controls, suggesting that the wheat plants were still utilizing nutrients stored in the seed.

Interestingly, wheat roots (Fig. 3-3d) treated with Fe-EDDHA show significantly higher Na concentrations compared to the control, both with and without *Pp* Pf-5 inoculation at EC of 1.3 dS·m⁻¹, and are not different from that under salinity stress. Based on the shoot and root dry masses, as well as shoot and root Na concentrations, it has been observed that wheat grown with Fe-EDDHA treatments takes up more Na, approximately 0.008 to 0.011 mg, in each magenta box compared to the negative controls. Moreover, the total additional Na contributed by Fe-EDDHA treatments is around 0.6 mg per magenta box, which is greater than the extra amount of Na uptake observed in wheat with these treatments. This suggests potential Na accumulation by the Fe-EDDHA (Sequestrene 138, C₁₈H₁₆FeN₂O₆·Na) treated wheat tissue.

Fig. 3-3. Shoot Fe (a), Na (b), root Fe (c), and Na (d) concentrations of wheat grown in the sand with four Fe treatments, control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA with and without inoculation by *Pp* Pf-5, with EC of 1.3 and 10 dS·m⁻¹. A three-way ANOVA was performed. Different letters above columns represent significant differences based on the Tukey test ($\alpha \leq 0.05$). Error bars represent the standard error calculated from the statistical mix model.

3.4.4 *Pp* Pf-5 colonization on root tissue observed via SEM

The influence of nano-metaVT and nano-CT-metaVT on the attachment of nano-metaVT and nano-CT-metaVT to the root surface and *Pp* Pf-5 colonization of the root

were observed by SEM. In Fig. 3-4, rod-shaped bacterial cells adhering to the surface of 14-day-old wheat roots inoculated with this bacterium are consistent with expectations for *Pp* Pf-5. These cells form clumps on all roots across different Fe and salinity treatments. In wheat grown with the control, nano-metaVT, and nano-CT-metaVT treatments under both normal and salinity stress conditions, the bacterial cells were linked to fine strands and small, rounded particles less than 100 nm in diameter, potentially extracellular vesicles as suggested by Potter et al. (2020). These vesicles might contain siderophores for scavenging Fe and other vital metals, similar to the cargo structures in extracellular vesicles of *P. aeruginosa* reported by Augustyniak et al. (2022), Couto et al. (2015), and Lin et al. (2017). It is also possible that the fine strands are drying artifacts from the extracellular polymeric substance (EPS). Bacterial cells and aggregates were also noted on roots treated with nano-metaVT and nano-CT-metaVT, as shown in Figs. 3-4b, 3-4c, 3-4f, and 3-4g, but were absent in roots treated with Fe-EDDHA. The study also revealed the presence of endophytes originating from within the wheat seeds, indicating a diverse microbial interaction in the growth system across the treatments (e.g., red arrows in Figs. 3-4d and 3-4h). EDS analyses of root particulate structures grown with nano-CT-metaVT under both normal and saline conditions (Figs. 3-4i and 3-4j) confirmed the presence of both Fe and P, consistent with the nano-CT-metaVT composition. However, this study does not observe the adherent of nano-metaVT or Fe-EDDHA on the root surface. These findings suggest that nano-metaVT, nano-CT-metaVT, and Fe-EDDHA would have a minimal impact on *Pp* Pf-5 root colonization under salinity stress.

Fig. 3-4. SEM images of the *Pp* Pf-5 colonization of wheat root surfaces when grown in sand with and without three different Fe sources and with and without salinity stress (EC = 1.3 dS·m⁻¹ versus (EC = 10 dS·m⁻¹) (a–h). Red arrows point out the presence of endophytes. EDS analyses for particles of nano-CT-metaVT attached to the root surface without salinity stress (i) and under salinity stress (j) are shown. The yellow squares are the targeted spots for EDS analyses.

The pore water of the sand inoculated with *Pp* Pf-5 was extracted, serially diluted, and cultured on a TSA medium. The bacterial colonies represent the number of bacterial cells living in the rhizosphere and released from the root surface if possible. The resulting bacterial concentrations (log CFU mL⁻¹) are depicted in Fig. 3-5, showing *Pp* Pf-5 levels ranging from 7-log to 8-log CFU mL⁻¹. Notably, wheat treated with nano-metaVT exhibited higher *Pp* Pf-5 concentrations than the control without salinity stress (EC = 1.3 dS·m⁻¹). Under saline conditions, however, nano-metaVT and nano-CT-metaVT treatments displayed no significant differences in *Pp* Pf-5 viable counts compared to the control.

Despite the presence of one or more endophyte(s) within the wheat seed (Figs. 3-4d and 3-4h), which persisted even after surface sterilization before sowing, the sand pore water cultures on TSA medium (Figs. B3-7a and B3-7b) exclusively showed *Pp* Pf-5 colonies. Siderophores are known to play a key role in enhancing the rhizosphere competence of root-colonizing bacteria (Roberto et al., 2007). This outcome suggests a competitive interaction between the *Pp* Pf-5 and endophyte, consistent with the root colonization patterns observed in Fig. 3-4. The findings suggest that the *Pp* Pf-5 population in the rhizosphere in the presence of nano-metaVT is higher than that of the negative control and not different from those of the nano-CT-metaVT and Fe-EDDHA treatments. However, the Fe-EDDHA treatment resulted in a higher bacterial concentration under salinity stress.

Fig. 3-5. Bacterial culturability of *Pp* Pf-5 in sand pore water extraction without salinity stress ($EC = 1.3 \text{ dS}\cdot\text{m}^{-1}$) and under salinity stress ($EC = 10 \text{ dS}\cdot\text{m}^{-1}$). A two-way ANOVA was performed. Different letters above columns represent significant differences based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated from the statistical mix model.

3.5 Conclusions

This study evaluates the role of *Pp* Pf-5 in supporting wheat growth in sand with high pH and salinity. Results show that nano-CT-metaVT and Fe-EDDHA treatments have longer shoots than the negative control; *Pp* Pf-5 inoculated wheat has longer shoots than wheat without microbial inoculation. Under salinity stress, *Pp* Pf-5 inoculated wheat has significantly higher transpiration rates than wheat grown without the microbe, suggesting mitigation of the salinity stress. Root colonization by *Pp* Pf-5 was evident, with bacterial cells forming clumps on roots and potentially extracellular vesicles that

might contain siderophores. Other wheat growth attributes, such as shoot/root dry mass and shoot/root Fe concentrations, resulted in no significant differences across Fe treatments, likely due to reliance on seed nutrients during the initial 14-day growth period. Still, these findings revealed the potential of multifunctional traits of *Pp* Pf-5, particularly in mitigating salinity stress in wheat growth under alkaline conditions. Future studies could further investigate the impact and mechanism of *Pp* Pf-5 inoculation on wheat growth under abiotic stress over an extended period.

CHAPTER 4

Exploring meta-vivianite and chitosan-coated meta-vivianite as alternative iron nano-fertilizers for plants growing in calcareous soil and the effects of salinity stress

4.1 Abstract

Calcareous soils are subject to several challenges, including high soil pH that leads to low iron (Fe) bioavailability and the constant threat of soil salinization due to low precipitation, high evapotranspiration, and repeated fertilization. Conventional synthetic Fe-chelates, such as Fe-EDDHA, are of concern due to their potential mobilization and leaching to groundwater. Metavivianite ($\text{Fe}^{\text{II}}\text{Fe}_2^{\text{III}}(\text{PO}_4)_2(\text{OH})_2 \cdot 6\text{H}_2\text{O}$; metaVT) has been applied to supply Fe to crops successfully. To enhance its efficacy, we propose applying nano-sized metaVT and coupling it with a beneficial surface coating, chitosan (CT), the second most abundant polysaccharide in the world. In this study, we examine the potential of nano-metaVT and nano-chitosan-coated metaVT (nano-CT-metaVT) as Fe sources for winter wheat (*Triticum aestivum* cv. Juniper) as the monocot and bush beans (*Phaseolus vulgaris*) as the dicot in calcareous soil. Our findings show that nano-CT-metaVT improves bean root dry mass, and nano-metaVT treatment increases the chlorophyll content of bean leaves. Nano-CT-metaVT results in lower Na uptake in shoot than Fe-EDDHA treatment, indicating a potential for salinity stress mitigation. Additionally, after 50 days, bean plants treated with nano-CT-metaVT showed increased flower and bud formation compared to controls. Fe mobility assessments revealed the retention of nano-metaVT in the top layer of soil, with a significantly higher DTPA-extractable Fe concentration than in the control soil. Notably, soluble Fe in the leachate was markedly lower for metaVT and CT-metaVT than for Fe-

EDDHA treatments, indicating less Fe leaching out from the soil column. The stability of metaVT and CT-metaVT in soil was confirmed over four weeks with wheat cultivation and confirmed with energy-dispersive X-ray spectroscopy (EDS). These findings suggest that metaVT and CT-metaVT are promising Fe fertilizers, offering environmental benefits and improved wheat and beans growth.

Keywords: beans, chitosan coating, iron deficiency, salinity stress, metavivianite, wheat

4.2 Introduction

Calcareous soils are subject to several challenges, including high soil pH that leads to low nutrient bioavailability and the constant threat of soil salinization due to low precipitation, high evapotranspiration, and the application of fertilizers and other soil amendments. Current agricultural production relies on chemical fertilizers to fulfill the growing demand for food (Zhang et al., 2015); however, low nutrient use efficiency and over-application of chemical fertilizers reduce crop yields and threaten soil health (Fess et al., 2011). For this reason, there is great interest in investigating nano fertilizers. With a high surface area to volume ratio, nano fertilizers exhibit distinct properties from conventional bulk fertilizers and are purported to increase fertilizer use efficiency by reducing required doses by minimizing volatilization and leaching losses (El-Ghany et al., 2021; Sadati Valojai et al., 2021; Solanki et al., 2015).

Iron (Fe) is an essential micronutrient (Kim and Guerinot, 2007). It is a co-factor for about 140 enzymes participating in metabolic processes such as photosynthesis, chlorophyll biosynthesis, and respiration (Brittenham, 1994; Kobayashi and Nishizawa, 2012; Morrissey and Guerinot, 2009). In calcareous soils, however, Fe deficiency is

common in plants (Abadia et al., 2011) because it is quickly rendered unavailable by reaction with hydroxide as pH increases. The free Fe^{3+} concentration in aerated-soil solutions is around $10^{-21.3}$ M at pH 8, and total soluble iron is $10^{-10.2}$ M, which is orders of magnitude less than the concentration required by crops (10^{-6} to 10^{-5} M in the soil solution) for optimal growth (Schenkeveld, 2010).

Conventional amendment with synthetic Fe-chelates is currently the most effective agricultural practice for preventing Fe deficiencies in calcareous soils (Rajaie and Tavakoly, 2018). However, a study by Hernandez-Apaolaza and Lucena (2011) using a 50 cm-long soil column (sandy loam, pH 7.7) to evaluate the soluble and retained fractions of Fe-EDDHA moving through soil found that over 25% of Fe-*o,o*-EDDHA was leached from the soil columns within ten days. Schenkeveld et al. (2012) found a 65% decline in the Fe concentration of soil solutions in extracts of Fe-EDDHA amended soils within one day, likely due to its sorption to organic matter, Fe(hydr)oxides, and clay minerals. Moreover, one of the Fe-EDDHA components, *o,p*-Fe-EDDHA, revealed a tendency to exchange Fe for Cu. This implies potentially high-risk mobilization and subsequent leaching of metals into the groundwater. Therefore, researchers are still looking for alternative Fe fertilizers that are environmentally friendly (Abadia et al., 2011).

In recent years, there has been a growing interest in vivianite due in part to its recoverability from wastewater and its potential as a Fe amendment for crop cultivation (Ammari and Hattar, 2011; Fodoue et al., 2015; Liu et al., 2018). Vivianite ($\text{Fe}^{\text{II}}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$; VT) is an iron phosphate mineral that usually occurs in reduced sediments. The partially oxidized form of vivianite, metavivianite

($\text{Fe}^{\text{II}}\text{Fe}_2^{\text{III}}(\text{PO}_4)_2(\text{OH})_2 \cdot 6\text{H}_2\text{O}$; metaVT), is more common in aerobic environments where the mixed oxidation state of Fe remains stable for extended periods of time (Rouzies and Millet, 1993). MetaVT is reported to be a promising alternative Fe fertilizer, as seen in studies with chickpeas (*Cicer arietinum* L.) and grapes (*Vitis vinifera*) growing in calcareous soils that reported similar leaf chlorophyll contents and yields as the Fe-EDDHA treated crops and significantly higher amounts than the controls (Bavaresco et al., 2010; Eynard et al., 1992).

Since nano-metaVT has a negative surface charge, we coated the nano-metaVT with chitosan (CT), a biodegradable, low-cost, non-toxic biopolymer that has been used as a beneficial surface coating on other nanoparticles (NPs) to impart a positive surface charge to the particles (Mikula et al., 2020; Modi et al., 2021; Sikder et al., 2021). We investigated how the CT coating affects Fe uptake by plants, Fe transport, and the weathering of the NPs applied in soil environments. In addition to simply correcting a nutrient deficiency, supplying crops with Fe has been shown to mitigate salinity stress in crops resulting, for example, in greater shoot and dry masses of *Medicago ciliaris* L. or increasing the protein and antioxidant activity of grapes (Rabhi et al., 2007; Mozafari et al., 2018). Therefore, we investigate whether the use of nano-meta-VT and nano-CT-metaVT are also effective at mitigating salinity stress in plants.

Finally, since plants have evolved two different strategies to uptake Fe, we will investigate both a siderophore-producing monocot (strategy 2) and a rhizosphere-acidifying dicot (strategy 1) to investigate whether there is a difference in their abilities to take up Fe from nano-metaVT or nano-CTmetaVT. We study winter wheat (*Triticum aestivum* cv. Juniper) as the monocot due to its agricultural importance in semi-arid

regions and bush beans (*Phaseolus vulgaris*) as the dicot due to its sensitivity to iron deficiency. We hypothesize that nano-metaVT and nano-CT-metaVT will improve Fe uptake growth attributes such as shoot length and root biomass, and mitigate the salinity stress in wheat and beans grown for 28 days. Results indicated that nano-CT-metaVT improves bean root dry mass, and nano-metaVT treatment increases the chlorophyll content of bean leaves. Nano-CT-metaVT results in lower Na uptake in shoot than Fe-EDDHA treatment, indicating a potential for salinity stress mitigation. Additionally, nano-metaVT and nano-CT-metaVT increased flower and bud formation in beans grown to maturity (50 days) compared to controls. This study provides insight into the effectiveness of nano-metaVT and nano-CT-metaVT as potential Fe fertilizers for wheat and beans growing in calcareous soils typical of semi-arid to arid regions.

4.3 Materials and Methods

4.3.1 Characterization of soil

The soil used in this study is from the Millville soil series (coarse-silty, carbonatic, mesic Typic Haploxerolls), collected from the Utah Agricultural Experiment Station Greenville Research Farm in North Logan, UT, USA, in April 2020 and internally designated as AgrM. The soil was collected from conventionally-managed wheat breeding plots planted and irrigated in a wheat-alfalfa rotation. The soil characteristics, including soil texture, particle size distribution, pH, EC, organic matter content, calcium carbonate equivalent, cation exchange capacity, phosphorus, potassium, ammonium, nitrate, sulfate, and other element concentrations, were analyzed using standard methods for the western region (Gavlak et al. 2005) and are provided in Table 4-1.

Table 4-1. Characteristics of soil sampled from 0–10 cm.

Characteristics	
Location	N 41.76346° W 111.81396°
Elevation	1369 m
Soil abbreviation	AgrM
Soil series, texture	Millville, silt loam
Taxonomic class	Coarse-silty, carbonatic, mesic Typic Haploxerolls
Particle size distribution (% sand/silt/clay)	22/56/23
Management	Irrigated commercial-style production
Crops	Winter wheat and small grain breeding trials in rotation with alfalfa
pH _{saturated paste extract}	8.4
EC _e (dS·m ⁻¹)	0.4
Phosphorus (mg kg ⁻¹)	12.0
Potassium (mg kg ⁻¹)	93.9
Ammonium (mg kg ⁻¹ N)	2.4
Nitrate (mg kg ⁻¹ N)	7.1
Sulfate (mg kg ⁻¹ S)	3.6
Organic matter (% of whole soil)	3.0
Cation exchange capacity (cmol kg ⁻¹)	20
Calcium carbonate (%)	14.1
Saturation point (%)	41.0
DTPA – Fe (mg kg ⁻¹)	6.0
DTPA – Cu (mg kg ⁻¹)	1.0
DTPA – Mn (mg kg ⁻¹)	12.3
DTPA – Zn (mg kg ⁻¹)	1.1

EC_e: Electrical conductivity of saturated paste extract

4.3.2 Wheat and beans grown in a growth chamber

4.3.2.1 Preparation of plant seeds and growth pots

Winter wheat (*Triticum aestivum* v. Juniper) and bean (*Phaseolus vulgaris*) seeds were surface-disinfected in fresh 10% H₂O₂ for 15 minutes, then rinsed ten times using sterile double-deionized water (resistance >18 MΩ cm). Ten seeds selected at random were placed on LB plates, sealed with Parafilm, and incubated at 23 °C for 48 h to confirm the absence of microbial contaminants. Soil was mixed with nano-metaVT, nano-CT-metaVT, and Fe-EDDHA (Sequestrene™ 138 Fe) at a dose of 5 mg/kg Fe and fertilized with 71.4 mg kg⁻¹ NH₄NO₃, 47.9 mg kg⁻¹ KH₂PO₄, and 52.9 mg kg⁻¹ KCl based on Utah Fertilizer Guide (James and Topper, 1993), to provide sufficient N, P, and K for the 28-day growth period. Each pot was filled with 2 kg of the amended soil. The experiment was conducted in pots (height: 18 cm; diameter: 15 cm) using a 4 × 2 factorial design with 8 treatments for each plant, wheat and bean, and three replicates. The variables were unamended controls; the presence/absence of the Fe sources metaVT, CT-metaVT, or Fe-EDDHA, each at 5 mg Fe kg⁻¹; wheat (monocot)/bean (dicot); and the presence/absence of salinity stress. The effectiveness of nano-metaVT and nano-CT-metaVT is expected to be better than that of the positive control (without Fe) and comparable to the positive control, Fe-EDDHA.

4.3.2.2 Growth conditions and the salinity stress treatment

Ten (wheat) and two (bean) sterilized seeds were placed in soil at an approximate depth of 5 mm. Wheat and beans were grown for 28 d at 25 ± 2 °C in a growth chamber under high-energy sodium lights (Yescom USA Inc.; City of Industry, CA, USA) and

fluorescent lamps (F54W/T5/841/ECO, GE 46761) with 16/8 h photocycle periods. The light panels were fixed at approximately 70 cm above the base of the pots, resulting in an average photon flux of $280 \mu\text{mol m}^{-2} \text{s}^{-1}$ at the top of the pot. The plants were irrigated with deionized water to field capacity gravimetrically for the first seven days; after that, the non-salinity treatments were watered with deionized water, and salinity treatments were watered with a saline solution containing 33.6 mM NaCl and 16.8 mM CaCl₂ (EC = $4 \text{ dS}\cdot\text{m}^{-1}$) for the next 21 days. The field capacity was measured with a soil tensiometer. The matrix is considered to be at field capacity when the water potential in the soil is at -33 kPa.

4.3.2.3 Determination of growth attributes

At 28 days post-sowing, plants were carefully uprooted from the soil. The root-adhering soil, referred to as rhizosphere soil, was distinguished from the bulk soil for subsequent analyses. To separate the rhizosphere soil from the root tissues, the roots were immersed in 100 mL of double-deionized water (resistivity $>18 \text{ M}\Omega\cdot\text{cm}$) in a 250-mL polycarbonate centrifuge bottle for one minute. Subsequently, the roots were placed on a clean paper towel to remove excess water. The wet weights of the shoot and root tissues were determined immediately after the lengths were measured. The shoot and root tissues were oven-dried at 60 °C for at least 48 h before the dry masses were weighed and recorded. The pH and EC of the oven-dried (60 °C) rhizosphere soil were measured in a soil suspension (soil: water = 1:1) prepared with double-deionized water (resistance $> 18 \text{ M}\Omega \text{ cm}$). The pH and EC of air-dried bulk soil were measured in a soil-saturated paste ($0.36 \text{ g H}_2\text{O g}^{-1} \text{ soil}$) extract prepared with double-deionized water.

4.3.2.4 Leaf chlorophyll relative content

Non-destructive estimation of the leaf chlorophyll concentration was made with a handheld chlorophyll meter (SPAD 502, Minolta Co. LTD, Osaka, Japan) on six leaves per pot on the 27th day after sowing.

4.3.2.5 Elemental analysis of plant tissue

To analyze shoot and root tissue for Fe, P, Na, and K concentrations, the dried plant tissue was weighed (about 0.2 g) and digested with nitric and perchloric acids based on the method described by Zasoski and Burau (1977). The digested samples were filtered through a 25 mm nylon syringe filter with a 0.22 μm pore size (Thermo Scientific, Waltham, MA, USA) and stored in scintillation vials. The Fe, P, Na, and K concentrations in the digested solution were determined by inductively coupled plasma mass spectrometry (Agilent 7700x Agilent Technologies, Santa Clara, CA, USA).

4.3.3 Fe mobility and leaching through the soil columns

To examine the Fe mobility of nano-metaVT, nano-CT-metaVT, and Fe-EDDHA through the calcareous AgrM soil, a polypropylene plastic cylinder (diameter = 5 cm; height = 15 cm) connected to a polyethylene support at the bottom with a drainage hole was used to hold soil (Fig. 4-1). A sheet of nylon mesh filter with a pore size of 30 μm was placed between the soil and the drainage hole. The columns were filled with 310 g of soil amended with 71.4 mg N kg^{-1} , 47.9 mg P kg^{-1} , and 100.8 mg K kg^{-1} . A subsample of Fe-enriched soil was prepared by adding nano-metaVT, nano-CT-metaVT, or Fe-EDDHA to a dose of 160 mg Fe kg^{-1} soil. Ten grams of the Fe-enriched soil was placed on the top (0.4 cm thick) of each 310 g soil column, resulting in an overall dose of 5 mg

Fe/kg per soil column (total mass 320 g). Half of the soil columns were planted with three surface-sterilized wheat seeds, half were left fallow, and all were watered daily to 1.2 times the field capacity of soil ($166.7 \text{ g H}_2\text{O kg}^{-1}$ soil) based on the weight of the whole column. No liquid leached out from the soil columns during days 1 to 9. On days 9 to 14, the soil columns were watered to 2.25 times the field capacity of soil ($312.5 \text{ g H}_2\text{O kg}^{-1}$ soil), and leachates were collected from days 10 to 15. The leachate was filtered through a 25 mm nylon syringe filter with a $0.22 \mu\text{m}$ pore size (Thermo Scientific) and stored in scintillation vials. The total soluble Fe in the leachate was determined by an inductively coupled plasma mass spectrometer (Agilent 7700x, Agilent Technologies). On Day 15, the soil was extruded from the plastic sleeves and divided into five layers with a thickness of 3 cm. Soil from each layer was analyzed for total and plant-available (DTPA extractable) iron.

Fig. 4-1. Illustration for the experimental set-up to examine Fe mobility and leaching through the soil columns.

The DTPA extract solution was prepared by dissolving 7.45 g triethanolamine (TEA), 0.985 g diethylenetriaminepentaacetic acid (DTPA), and 0.735 g $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ in 20 mL ddH₂O. Then, the solution was diluted to about 400 mL with ddH₂O, adjusted to pH 7.3 ± 0.05 with 1.0 M HCl, and diluted to 500 mL with ddH₂O. Then, 10 g of soil was weighed into 50 mL centrifuge bottles, and 20 mL DTPA extract solution was added to each tube. Samples were shaken for 2 h at 180 rpm and then centrifuged at $17,000 \times g$ for 25 minutes. After centrifuging, the supernatant from each sample was filtered through a $0.22 \mu\text{m}$ nylon filter into a separate scintillation vial. The solution was analyzed for Fe

using an atomic absorption spectroscopy (AAS, Varian AA240, Agilent Technologies, Santa Clara, CA, USA), with a wavelength of 248.3 nm, slit width of 0.2 nm.

4.3.4 Weathering of nano-metaVT and nano-CT-metaVT in soil

The weathering of nano-metaVT and nano-CT-metaVT in the soil with the presence of wheat roots was investigated by scanning electron microscopy (SEM). A small piece of double-sided carbon tape was adhered to an aluminum specimen stub (diameter = 125 mm) and sprinkled with nano-metaVT or nano-CT-metaVT powder (Fig. 4-2). The treated stubs were then buried in a 50-mL conical centrifuge tube filled with soil. One sterilized wheat seed was planted in each tube and watered daily. At 1, 2, 3, and 4 weeks after sowing, the stub in each treatment was excavated, air-dried, and readied for SEM examination. The samples were sputter-coated gold and palladium to form a 10-nm layer using a rotary sputter coater system EMS150R ES (Electron Microscopy Sciences, Hatfield, PA, USA). The morphology of the particles was viewed in a SEM (Quanta FEG 650, Field Electron and Ion Company, Hillsboro, OR, USA) under a high vacuum at an accelerating voltage of 20 kV. The Fe/P weight ratio of nano-metaVT and nano-CT-metaVT in soil was identified by EDS.

Fig. 4-2. The experimental set-up for examining the weathering of nano-metaVT and nano-CT-metaVT in a calcareous soil planted with wheat.

4.3.5 Data analysis

The experimental design for the wheat and bean growth study was structured according to a randomized complete block design (RCBD) with three trials (block) per treatment. Three trials (block) were conducted, resulting in nine experimental units ($n = 9$) per treatment. Plant growth parameters, physiological measurements, and elemental analyses were subjected to statistical evaluation using a two-way Analysis of Variance (ANOVA) performed with SAS software (SAS[®] Studio, release 3.81, Enterprise Edition, Madison, WI, USA). Diagnostics of residuals did not reveal a departure from normality and nonconstant variances, except for EC values of the rhizosphere and bulk soils, shoot and root Na concentration, and wheat root dry masses, which were all log-converted prior to the data analysis. The adjusted Tukey-Kramer multiple comparison procedure was

employed to discern significant differences between treatment means, with a significance level set at 0.05.

For the beans grown to maturity (50 days), the Fe mobility and leaching experiment, and the nano-metaVT and nano-CT-metaVT weathering experiments, a completely randomized design (CRD) was implemented with three replications ($n = 3$). Diagnostics of residuals did not reveal a departure from normality and nonconstant variances. The adjusted Tukey-Kramer multiple comparison procedure was employed to discern significant differences between treatment means, with a significance level set at 0.05.

4.4. Results and Discussions

4.4.1 Growth attributes of wheat and bean grown in soil

After 28 days of soil cultivation, the growth attributes (shoot/root dry masses, shoot water content, and chlorophyll content) of wheat and beans grown with the nano-metaVT, nano-CT-metaVT, and Fe-EDDHA treatments were assessed. Figs. 4-3a and 4-3b show no significant effect of Fe sources on shoot dry masses of wheat and beans, including the positive control, Fe-EDDHA. On the other hand, Fe-EDDHA treatment shows a greater wheat root dry mass than the control without the salinity stress but not under the salinity stress (Fig. 4-3c). In Fig. 4-3d, the nano-CT-metaVT treatment resulted in a higher root dry mass of beans than the control and was not different from Fe-EDDHA. The results indicate the effect of different Fe sources is more significant in wheat/bean root tissue than in shoot tissue.

Fig. 4-3. Shoot dry mass (a, b) and root dry mass (c, d) of wheat and beans grown with four Fe treatments, control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA, and irrigated with ddH₂O or saline water ($EC = 4 \text{ dS}\cdot\text{m}^{-1}$). A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Wheat grown with the nano-metaVT amendment displays superior shoot water content compared to the Fe-EDDHA treatment (Fig. 4-4a). According to previous research, shoot water contents measured four weeks after sowing wheat correlate positively to grain yields (Tahara et al., 1990). The consequences of the various Fe treatments on the relative chlorophyll content of beans are presented in Fig. 4-4d. Beans treated with nano-metaVT exhibit increased chlorophyll contents compared to the control. In a similar study using a dicotyledon plant, Rosado et al. (2002) assessed the impact of vivianite on olive trees (*Olea europaea* L.) cultivated in calcareous soil (pH 8.1–8.6) with doses of vivianite (not nano-sized) ranging from 0.5 to 2 kg tree⁻¹. Their results indicate that vivianite is nearly as effective as Fe chelate in mitigating Fe chlorosis in olive trees, with the effects lasting over two years. In contrast, the chlorophyll contents of wheat remain consistent, about 36.6 ± 3.6 , across all treatments (Fig. 4-4c). This observation aligns with the findings of Naz et al. (2023), who treated wheat grown in calcareous soil (pH 7.7; DTPA-extractable Fe: 5.23 mg Fe kg⁻¹) with FeSO₄·7H₂O at agriculturally relevant concentrations of 5.7 and 8.5 mg Fe kg⁻¹, but found no significant difference in chlorophyll content. In summary, applying nano-metaVT demonstrates the potential to increase the chlorophyll contents of beans but not wheat.

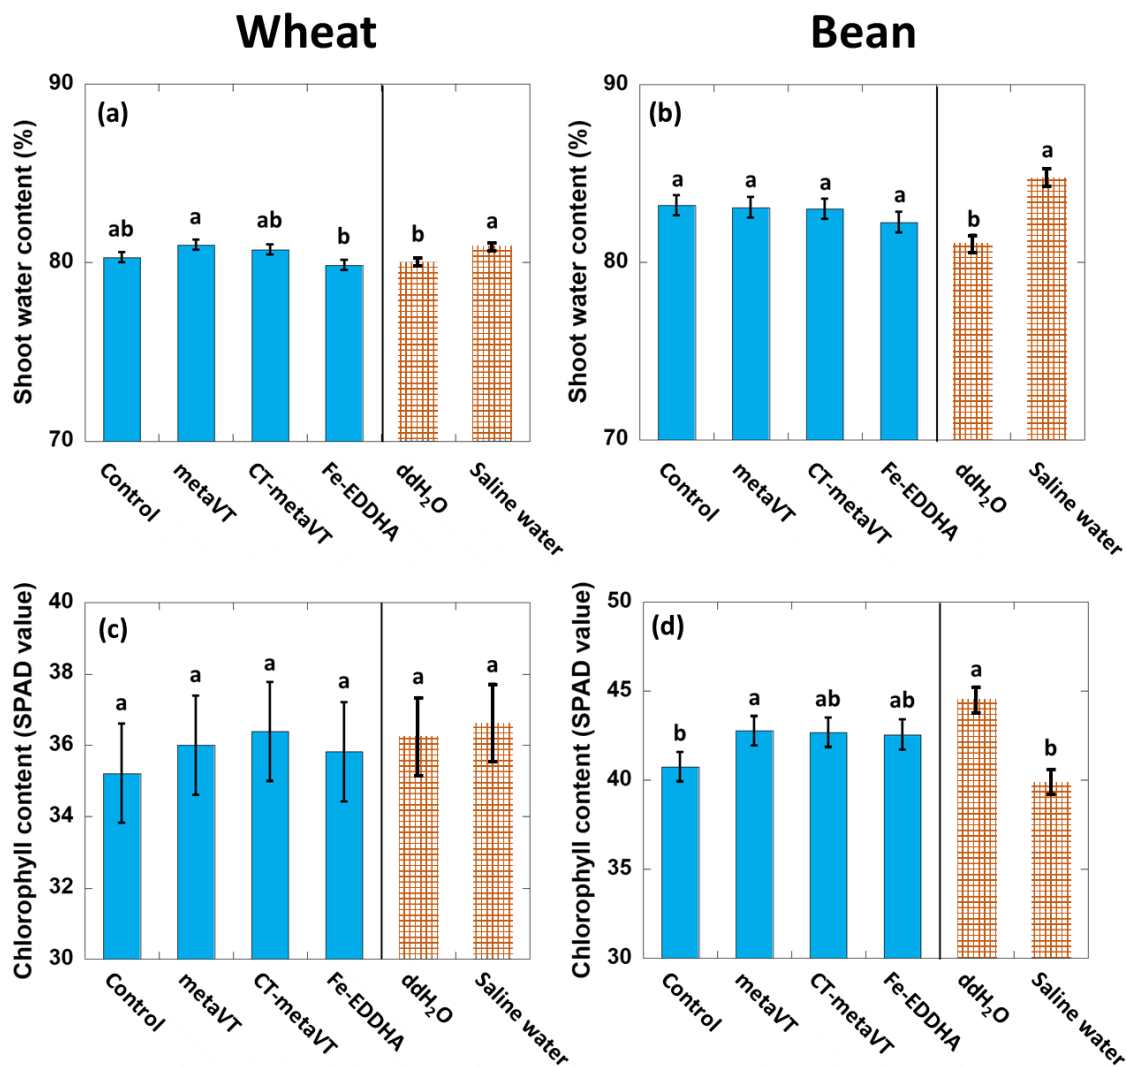

Fig. 4-4. Shoot water content (a, b) and relative chlorophyll content (c, d) of wheat and beans grown with four Fe treatments: control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA, and irrigated with ddH₂O or saline water ($EC = 4 \text{ dS} \cdot \text{m}^{-1}$). A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

4.4.2 Elemental analysis of plant tissue

As seen in Fig. 4-5a, for wheat grown for 29 days, the applications of various Fe amendments did not significantly affect shoot Fe concentrations. However, the nano-metaVT treatment resulted in a higher shoot P concentration than the Fe-EDDHA treatment. Interestingly, the salinity treatment results in higher Fe but not P concentrations in wheat shoots (Figs. 4-5b and 4-5c). In beans, on the other hand, the Fe-EDDHA treatment results in higher shoot Fe but not P concentrations, and the salinity treatment did not affect shoot Fe nor P concentrations (Figs. 4-5 b and 4-5d).

Fig. 4-5. Shoot Fe (a, b) and P (c, d) concentrations of wheat (a, c) and beans (b, d) grown in soil with four Fe treatments, control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA, and irrigated with ddH₂O and saline water (EC = 4 dS·m⁻¹). A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figs. 4-6a and 4-6c show that the nano-CT-metaVT-treated wheat resulted in a significantly lower shoot Na concentration and a higher shoot K concentration than the Fe-EDDHA treatment. However, the shoot Na concentration in beans is not affected by the different Fe sources. CT-metaVT-treated beans had a lower shoot K concentration than the control. The connection between Fe availability and K uptake is highlighted by Milashi et al. (2020), who suggest that enhanced Fe uptake promotes K absorption, leading to increased K uptake. Na⁺ and K⁺ ions engage in competitive interactions for absorption via shared transport mechanisms. This competition is frequently skewed in favor of Na⁺ due to its typically higher extracellular concentration relative to K⁺ in saline conditions, which enhances the uptake efficiency of Na⁺ over K⁺. This reduction potentially facilitates the activation of defense pathways, including antioxidative enzymatic systems, such as catalase and superoxide dismutase (Naz et al., 2023).

Fig. 4-6. Shoot Na (a, b) and K (c, d) concentrations of wheat (a, c) and beans (b, d) grown in soil with four Fe treatments, control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA, and irrigated with ddH₂O and saline water ($EC = 4 \text{ dS}\cdot\text{m}^{-1}$). A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

The root-associated Fe concentrations of the nano-metaVT and nano-CT-metaVT-treated wheat are significantly higher than those treated with Fe-EDDHA t (Fig. 4-7a) though none of the root-associated Fe concentrations of the Fe-treated wheat were significantly different than the negative control. Thus, the Fe sources do not affect the root-associated Fe in beans. Moreover, no significant changes are observed in root-associated P, Na, and K concentrations with any of the Fe treatments (nano-metaVT, nano-CT-metaVT, and Fe-EDDHA) of wheat and bean (Fig. B4-1). In this study, employing a highly calcareous soil, the effects of Fe treatments on shoot and root-associated Fe are more significant in wheat (monocot), which employs siderophores to acquire Fe, than for the rhizosphere-acidifying beans (dicot). In addition, decreased Na and increased K uptake in shoot compared to Fe-EDDHA treatment are observed in the nano-CT-metaVT-treated wheat but not in beans. The effects of nano-(meta)vivianite on wheat and beans under salinity stress have not been explored before, based on the literature summarized in Table 4-2, and warrant further investigation.

Fig. 4-7. Root-associate Fe (a, b) of wheat and beans grown with four Fe treatments, control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA, and irrigated with ddH₂O or saline water (EC = 4 dS·m⁻¹). A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Table 4-2. Examples of the effectiveness of (meta)vivianite on various plants grown under high pH or calcareous conditions.

Material	Dose	Growth conditions	Plants	Effectiveness	References
Nano-metaVT, Nano-CT-nano-metaVT	5 mg Fe kg ⁻¹	calcareous, pH 8.4	Winter wheat (<i>Triticum aestivum</i> v. Juniper) and bean (<i>Phaseolus vulgaris</i>)	Nano-CT-metaVT showed an increase in root dry mass and relative chlorophyll content of beans. In addition, there are higher numbers of flowers and buds in nano-CT-metaVT-treated beans grown for 50 days than in the negative control.	This study
vivianite	1 g kg ⁻¹	pH 8.2-8.5	Chickpea (<i>Cicer arietinum</i> L.)	The chlorophyll content of chickpea leaves was improved with the application of vivianite.	(Eynard et al., 1992)
vivianite	0.5-2 kg per tree	calcareous, pH 8.1-8.6	Olive trees (<i>Olea europaea</i> L.)	Vivianite was almost as effective as Fe chelate in reducing Fe chlorosis in olives, lasting more than two years.	(Rosado et al., 2002)
vivianite	1.8 g kg ⁻¹	calcareous, pH 8.0	Kiwifruit (<i>Actinidia deliciosa</i> (A.Chev.) C.F.Liang and A.R.Ferguson)	Vivianite enhanced leaf chlorophyll content compared to control treatment under both greenhouse and field conditions.	(Rombola et al., 2003)
Fe sulfate, vivianite	0.08, 0.16, 0.32 g Fe kg ⁻¹	calcareous, pH value: NA	(<i>Lupinus albus</i> L.)	Vivianite improved the yield and chlorophyll content with long-term effects and was further enhanced by adding humic substances.	(de Santiago et al., 2008)
vivianite	25 g/L per pot	calcareous, pH 7.3	<i>Vitis vinifera</i> L. cv. Merlot grafted on lime-susceptible rootstock	Vivianite was as effective as Fe chelate (Fe-EDDHA) in improving the chlorophyll contents in grapevine leaves.	(Bavaresco et al., 2010)
synthetic vivianite	1.0 g kg ⁻¹	calcareous, pH 8.2	Rooted cuttings of <i>Vitis berlandieri</i> Resseguier No. 2 x <i>Vitis rupestris</i> Martin	The vines fertilized with vivianite had longer shoots and a higher number of leaves and exhibited higher SPAD values than the control vines. The effectiveness of vivianite lasts through 3 years, indicating the long-term fertilizing effect.	(Diaz et al., 2010)
synthetic vivianite	0.5-2.0 g kg ⁻¹	calcareous, pH 7.7	<i>Eureka lemon</i> (<i>Citrus lemon</i> L.) cuttings grafted on sour orange (<i>Citrus aurantium</i> L.)	Vivianite application exhibited a greater leaf Fe concentration and chlorophyll content than untreated plants. The effectiveness of vivianite was comparable to Fe-EDDHA.	(Ammari and Hattar, 2011)

4.4.3 Beans grown to maturity

The results presented in sections 4.4.1, 4.4.2, and 4.4.3 focus on beans cultivated for 28 days. Since a different growth duration might lead to different responses to the Fe treatments, the experiment was replicated with beans over a longer growth period of 50 days, and the outcomes are presented in Fig. 4-8. Both the nano-metaVT and nano-CT-metaVT treatments significantly influenced the flowering phase, leading to a noticeable rise in the number of flowers and buds compared to untreated controls (Fig. 4-8a). Additionally, beans subjected to the nano-CT-metaVT treatment manifested greater shoot lengths than the control (Fig. 4-8b). Moreover, the Fe-EDDHA-treated bean shows a greater root dry mass than the control (Fig. 4-8c). Interestingly, beans treated with nano-metaVT for 50 days exhibit a higher Fe concentration in shoot tissue relative to all other treatments (Fig. 4-8d). In contrast, on Day 50 of this experiment, the Fe-EDDHA treatment resulted in significantly higher Fe concentrations in the bean pods and the root tissues compared to the control. This study highlights the promising potential of nano-metaVT and nano-CT-metaVT treatments in boosting flowering and possibly future yield in beans. The results spanning over the 28 and 50-day growth periods accentuated that the distinctions in overall growth become more pronounced with prolonged growth duration. At the 50-day mark, the beans were observed to be in the flowering stage, with promising bean pods.

Fig. 4-8. Beans grown in soil with four Fe treatments (control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA) for 50 days. A one-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard deviation of the three replicates.

4.4.4 Fe mobility and leaching through the soil columns

We confirmed the decreased mobility of nano-metaVT and nano-CT relative to Fe-EDDHA using soil columns planted with wheat. Since the calcareous soil has a high total Fe concentration, DTPA-extractable Fe (defined as plant-available Fe) was used to investigate differences in the treated soil columns. Table 4-3 presents the DTPA-extractable Fe concentrations across various depths of the soil columns separated into five layers. The initial DTPA-extractable Fe concentration of the untreated soil is $6.0 \pm 0.2 \text{ mg kg}^{-1}$. The surface layer treated with Fe-EDDHA exhibits a tenfold higher DTPA-extractable Fe concentration ($114.7 \pm 10.9 \text{ mg kg}^{-1}$) than those treated with nano-metaVT ($10.0 \pm 0.7 \text{ mg kg}^{-1}$) and nano-CT-metaVT ($10.6 \pm 0.3 \text{ mg kg}^{-1}$). This notable disparity is attributed to the high solubility of iron chelates. After 14 days, columns treated with both nano-metaVT and nano-CT-metaVT show the highest DTPA-extractable Fe concentrations at the surface layer, surpassing those in the deeper soil layers. In contrast, Fe-EDDHA treated columns display no significant variation in DTPA-extractable Fe concentrations among the different layers, with values ranging from 6.5 to 7.5 mg kg^{-1} . These findings also highlight the rapid depletion of DTPA-extractable Fe in the Fe-EDDHA-treated columns compared to the high initial DTPA-extractable Fe concentration in the top layer.

Fig. 4-9 shows that the total soluble Fe in the leachate from columns treated with nano-metaVT is 0.57 μg accumulated over D11 to D15. The total soluble Fe concentration in the nano-CT-metaVT treated column leachate is 1.01 μg accumulated over D11 to D15, which is not different from nano-metaVT treatment. In comparison, the total soluble Fe is 23.57 μg in the leachate of the Fe-EDDHA-treated column

accumulated over D11 to D15, significantly higher than the control, nano-metaVT, and nano-CT-metaVT treated column leachates. The results confirm that Fe-EDDHA leaches more readily from the soil profile than nano-metaVT and nano-CT-metaVT. A study by Hernandez-Apaolaza and Lucena (2011) used soil (sandy loam, pH 7.7) in a 50 cm-long column to evaluate the soluble and retained fractions of Fe-EDDHA moving through soil. A single 2 mL dose of 500 mg Fe L⁻¹ solutions of Fe-EDDHA was poured onto the top of the columns at the beginning of the experiment, and over 25% of Fe-o,o-EDDHA was leached from the soil columns within ten days. The results imply potentially high-risk mobilization and subsequent leaching of Fe-EDDHA into the groundwater, resulting in inefficient plant utilization rates and an increased risk of environmental pollution.

Table 4-3. The mobility of DTPA-extractable Fe in the soil columns with wheat. Two-way ANOVA with differing letters represents a significant difference based on the Tukey-Kramer test ($\alpha \leq 0.05$).

unit: mg kg ⁻¹	control	metaVT	CT- metaVT	Fe-EDDHA
Initial DTPA-Fe concentrations in the top layers (0.4 cm; 160 mg Fe kg ⁻¹)	6.0 ± 0.2	10.0 ± 0.7	10.6 ± 0.3	114.7 ± 10.9
Layer 1	6.9 ± 0.4 ^{bcd}	8.2 ± 0.3 ^a	7.9 ± 0.3 ^{ab}	7.5 ± 0.6 ^{abc}
Layer 2	6.0 ± 0.2 ^d	6.5 ± 0.2 ^{cd}	6.7 ± 0.2 ^{cd}	6.5 ± 0.1 ^{cd}
Layer 3	6.0 ± 0.3 ^d	6.4 ± 0.2 ^{cd}	6.5 ± 0.1 ^{cd}	6.7 ± 0.2 ^{cd}
Layer 4	6.2 ± 0.1 ^d	6.7 ± 0.4 ^{cd}	6.7 ± 0.1 ^{cd}	7.4 ± 0.9 ^{abc}
Layer 5	6.2 ± 0.2 ^d	6.9 ± 0.4 ^{bcd}	6.6 ± 0.0 ^{cd}	7.5 ± 0.7 ^{abc}

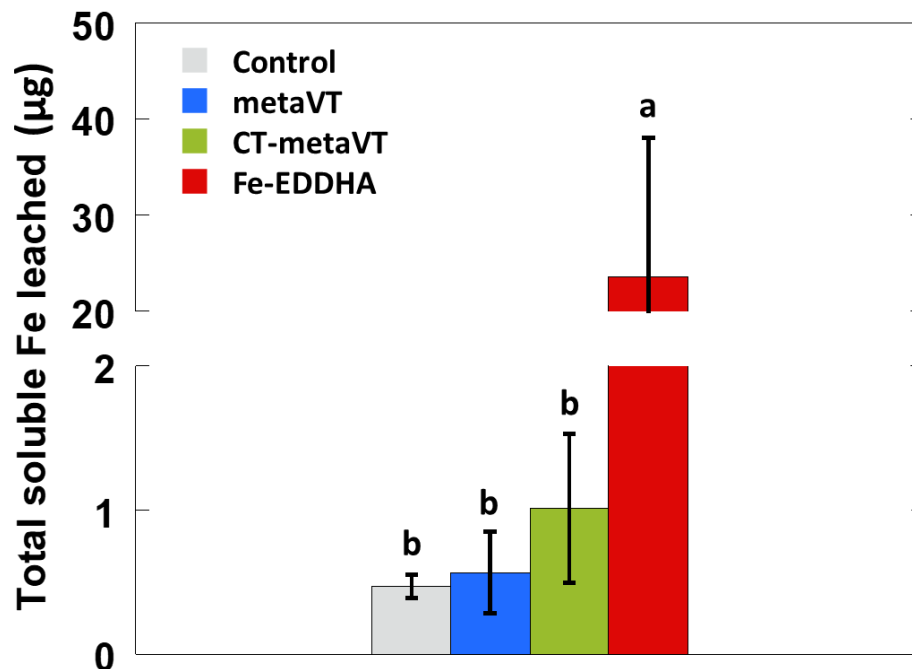

Fig. 4-9. The total soluble Fe leached from day 11 to day 15 through soil columns planted with wheat. A one-way ANOVA was performed. Different letters above the columns represent significant differences based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard deviation of the three replicates.

4.4.5 Weathering of nano-metaVT and nano-CT-metaVT in soil

Fig. 4-10 illustrates the weathering profiles of nano-metaVT and nano-CT-metaVT in soil from one to four weeks after planting with wheat. Both nano-metaVT and nano-CT-metaV retained their morphology throughout the four weeks, displaying no significant dissolution or breakdown. The Fe/P mass ratio of both nano-metaVT and nano-CT-metaVT in soils was determined by EDS, with results displayed in Fig. B4-4. Initially, the Fe/P atomic weight ratio of the applied nano-metaVT and nano-CT-metaVT was 2.7 (3Fe/2P). Over the four weeks, this ratio ranged between 3 and 4, aligning more closely with a ratio of 3.6 (2Fe/P). However, as the nano-metaVT and nano-CT-metaVT were in contact with soil and plant roots for several weeks, the potential attachment of other particles or compounds might have affected the semi-quantification of Fe or P by EDS. This uncertainty means that while the values appeared stable, the specific weathering reactions that occurred cannot be precisely determined.

Previous studies, such as that by Roldan et al. (2002), used 99.99% pure oxygen saturated with water to verify the final weathering product of bulk VT, as lepidocrocite (γ -FeO(OH)), an iron oxide-hydroxide mineral. The present findings show that neither nano-metaVT nor nano-CT-metaVT achieved complete oxidation within four weeks in planted and watered soil as indicated by the presence of P remaining in nano-metaVT and nano-CT-metaVT minerals. This suggests their potential for long-term effectiveness when applied as a soil amendment. Although the exact weathering rates of nano-metaVT and nano-CT-metaVT in soil remain unclear, our incubation results suggest they provide a stable source of Fe, potentially benefiting plant iron nutrition over extended periods.

These results support findings by Rosado et al. (2002), who documented the enduring positive impacts of vivianite in combating chlorosis in olive trees for up to two years.

Fig. 4-10. Morphology of nano-metaVT and nano-CT-metaVT weathered in soil planted with wheat for one to four weeks.

4.5 Conclusions

This study investigates mitigating the dual agricultural challenges of Fe deficiency and soil salinity in arid and semi-arid calcareous soils where inorganic Fe bioavailability is limited. The study confirms that nano-CT-metaVT improves bean root dry mass, and nano-metaVT treatment increases the chlorophyll content in beans. Compared with Fe-EDDHA treated plants, nano-CT-metaVT lowers Na uptake in shoot, indicating a potential for salinity stress mitigation. A notable increase in reproductive potential, as indicated by a higher number of flowers and buds, was observed for beans to maturity (50 days), with a higher number of flowers and buds. Nano-metaVT demonstrates superior environmental performance by minimizing Fe leaching, as evidenced by its retention in the soil and lower concentrations of soluble Fe than Fe-EDDHA leachates. Stability tests over four weeks further validate the utilization of nano-

metaVT and nano-CT-metaVT as stable and subject to less loss via leaching the FeEDDHA.

CHAPTER 5

LITERATURE REVIEW II

5.1 Development of current disinfection approaches

Effective disinfection approaches are crucial in environmental management and water treatment.¹ Disinfection can control the spread of infectious diseases by eliminating harmful microorganisms from water, surfaces, and air.² In medical and healthcare settings, it is essential to prevent hospital-acquired infections and ensure the sterility of medical instruments.³ In water treatment, disinfection is vital to ensure safe drinking water free from pathogens such as bacteria, viruses, and protozoa, thereby preventing waterborne diseases.⁴ Conventional disinfection methods, including chlorination, UV light, and ozonation, have been well established. However, these methods also have disadvantages, such as the high cost of the raw chemicals, the generation of toxic byproducts, or low disinfection efficiency.^{5,6} In addition, pathogens develop resistance to traditional disinfectants, necessitating the ongoing development of effective disinfectants and promising new disinfection methods.⁷⁻⁹ Examples of conventional disinfection approaches and their disadvantages are listed below:

(a) Chlorine:

Chlorine is widely recognized as one of the most cost-effective and potent disinfectants for neutralizing microorganisms and maintaining residual concentration to inhibit microbial growth in water supply systems.¹⁰ Its affordability and widespread availability have established it as a mainstay in numerous municipal water treatment processes.¹¹ However, despite its apparent efficacy, chlorine has significant drawbacks. A

primary concern is the formation of disinfection byproducts.¹⁰ The interaction of chlorine with organic matter in water leads to the creation of harmful compounds such as trihalomethanes and haloacetic acids.¹² Epidemiological studies have associated prolonged exposure to these byproducts with various health issues, including the potential for carcinogenic effects.¹³

(b) UV radiation:

UV disinfection has gained popularity due to several advantages, such as its efficacy in inactivating pathogens, absence of disinfectant residuals, minimal formation of disinfection byproducts, and the ease with which it can be integrated into existing water treatment processes, or to sterilize surfaces such as medical equipment, the inside of biosafety cabinets and hoods, etc.¹⁴ However, it faces certain limitations. The complexity of substances in the treated water and economic constraints mean that UV doses might not always ensure the complete inactivation of antibiotic-resistant microbes. Additionally, UV disinfection lacks prolonged residual effects, and the possibility of photoreactivation and dark repair mechanisms can undermine its overall effectiveness.¹⁵ Consequently, in most practical applications, a combined approach is often necessary, where UV disinfection is used alongside another method that provides lasting residual protection to ensure comprehensive water safety.¹⁶

(c) Silver:

Silver (Ag) has a long-standing history of water disinfection, tracing centuries.¹⁷
¹⁸ Ag nanoparticles extend to various domains such as air and water purification, biomedical sector as therapeutic agents, consumer products in textiles, and wound

dressing applications.¹⁷ However, concerns have been raised regarding the leaching of Ag, particularly from fabric products, when exposed to various liquids like water, milk, sweat, and urine. Quadros et al. (2013) reported that leaching levels of Ag were higher with sweat and urine than with tap water.¹⁹ The potential for accumulation and concerns about human toxicity and environmental impacts from continuous Ag release necessitates careful management. Moreover, Ag has a strong affinity for binding with sulfur (S), both organic and inorganic, particularly in wastewater treatment plants.²⁰ As a result, most silver nanoparticles (Ag NPs) are effectively concentrated and subsequently removed during the treatment process.²¹ These factors limit the unrestricted use of Ag and emphasize the need for cautious application, especially in consumer products.²²

(d) Photocatalyst:

Photocatalysis has the potential to serve as an alternative technology due to its emerging ability to degrade persistent organic pollutants and inactivate pathogens effectively.²³ Because of its large band gap, titanium dioxide (TiO₂) is one of the most popular photocatalysts. Its versatility in water disinfection is impressive for degrading organic pollutants and inactivating bacteria, viruses, and other pathogens. The popularity of TiO₂ can be attributed to its cost-effectiveness and high oxidative potential. When illuminated by UV light, TiO₂ can produce reactive oxygen species (ROSs), which are highly reactive and can oxidize a wide range of contaminants. However, conventional TiO₂ can only be activated under radiation with wavelengths below 350 nm.²⁴ Moreover, photocatalysts have typically been used in suspension systems for photooxidation. The TiO₂ suspension process often suffers from the adverse effects of particle aggregation and turbidity shading in the catalyst suspension, thereby reducing its photocatalytic activity.

Another concern with using nano-sized photocatalysts is the difficulty of completely removing these particles from water after treatment, posing potential environmental and health risks.

(e) Waste-derived disinfection agents:

Waste-derived disinfection agents are gaining attention in a world grappling with increasing waste generation and the dire need for sustainable solutions. The idea is to utilize certain waste materials with antimicrobial properties as disinfection agents. For instance, waste from fishery sources, such as oyster shells or shrimp shells, can be processed to produce disinfection materials, which has shown potential in water disinfection. These agents function either by releasing antimicrobial substances or interrupting bacterial metabolism to inactivate pathogens. Beyond the obvious environmental advantage of repurposing waste, these agents can be cost-effective, especially in regions with abundant waste material. However, studies are needed to ensure the consistency of the waste-derived agent and optimize efficiency to match or surpass conventional disinfectants.

5.2 Role of titanium dioxide (TiO₂)

Advanced oxidation processes are popular technologies that utilize ROSs to degrade various contaminants in water.²⁵ Advanced oxidation processes have been indicated as one of the promising approaches in water purification from persistent organic pollutants²⁶, pharmaceutical residues²⁷, and even microorganisms. The procedures rely on the production of ROSs such as singlet oxygen (¹O₂), hydroxyl radicals (·OH), and hydrogen peroxide (H₂O₂). These strong oxidants can degrade recalcitrant compounds

through reactions involving, for example, Fenton catalysis^{28, 29}, ozonation³⁰, and sulfate radical-based reactions.^{31, 32} Hydroxyl radicals can also be initiated by photons in the presence of catalysts or oxidants. The most common catalyst is titanium dioxide (TiO₂).

TiO₂ functions as a semiconductor, and its photocatalytic activity is initiated by absorbing photons with adequate energy. This absorption causes electrons in the valence band (e_{vb}^-) of TiO₂ to be excited to the conduction band (e_{cb}^-), leaving behind positively charged holes in the valence band (h_{vb}^+).²⁴ The band gap energy of anatase, a form of TiO₂, is around 3.2 eV, indicating that photocatalysis is triggered by photons with wavelengths below approximately 385 nm, which falls within the UVA spectrum.³³ There are two possible pathways for these excited electrons and holes. They may undergo bulk recombination, a process where they simply recombine without contributing to photocatalytic activity, which is considered an unproductive reaction. Alternatively, when these electrons and holes reach the TiO₂ surface, they can participate in reactions that generate ROSs, such as superoxide anion radicals ($O_2^{\cdot-}$), $\cdot OH$, and H_2O_2 radicals.³⁴ These ROS are highly reactive and play a crucial role in the photocatalytic degradation of contaminants and inactivation of pathogens.

5.3 Improve the photocatalysis effectiveness

(a) Element doping

Much effort has been made to enhance the photocatalytic efficiencies of photocatalysts, such as doping and surface modification. Element doping of TiO₂ is one approach that can further narrow the bandgap, allowing it to utilize the full spectrum of visible light in sunlight.^{35, 36} Elemental doping involves introducing foreign atoms into

the TiO₂ lattice, which can modify its electronic structure and optical properties.³⁷ For example, doping with metals like iron (Fe)³⁸, Ag³⁹, and copper (Cu)⁴⁰ has been shown to narrow the band gap of TiO₂, allowing it to absorb visible light more effectively than the pure material, which primarily absorbs ultraviolet light. Metal doping can introduce new recombination centers, while non-metal doping might decrease photocatalytic activity under certain conditions.

Non-metal doping, with elements such as nitrogen (N)³⁵, carbon (C)⁴¹, and sulfur (S)⁴², also shows promise. The choice of dopant depends on the desired application and the specific properties required for the photocatalyst. Overall, elemental-doped TiO₂ has shown improved performance in various environmental and energy applications, including air and water purification, self-cleaning surfaces, and hydrogen production. It also extends the range of light that TiO₂ can utilize, enhancing its photocatalytic activity under solar illumination.

(b) Immobilization

Photocatalysts are commonly used in suspension systems for photooxidation, but TiO₂ suspensions often face challenges such as particle aggregation and turbidity shading, which diminish photocatalytic activity. Immobilizing photocatalysts onto surfaces can effectively mitigate these issues.⁴³ Immobilization involves fixing the catalyst powder onto a support material, offering a sustainable and cost-effective disinfection solution without the need for post-treatment steps, thus reducing operational costs.⁴⁴ Additionally, immobilized photocatalysts can be reused without the need for recovery or separation from the suspension, addressing ecotoxicity concerns.^{45, 46} Previous research has demonstrated the potential of immobilized TiO₂ for bacterial

inactivation. Cantarella et al. (2016) embedded TiO₂ in polymethyl methacrylate (PMMA) at a concentration of 150 g L⁻¹, achieving a 4.8-log reduction in *E. coli* in one hour under UV light.⁴⁷ Varnagiris et al. (2021) immobilized carbon-doped TiO₂ on high-density polyethylene (HDPE) beads, resulting in a 2.5-log reduction in *Salmonella typhimurium* in one hour under UV light (5 mW cm⁻²).⁴⁸ However, the efficiency of immobilized photocatalysts against bacteria under visible light and their comparison to suspension systems have not been extensively explored.

Poly-methyl-methacrylate (PMMA) has excellent impact strength, UV resistance, and high transparency to visible light. It is also the most frequently used commercial polymer in architecture, electronics, and furniture.^{49, 50} By sprinkling a layer of TiO₂ on PMMA fabricating a TiO₂/PMMA film, Ounas et al. (2020) showed that the photocatalytic degradation of methylene blue with UV light irradiation remained merely only 60% after 250 min because the sprinkling method reduced PMMA light transmittance by 50%.⁵¹ To improve the light transmittance, other researchers have adopted methods to functionalize the PMMA polymer matrix with the minimum influence on its original properties, including dip-coating⁵², vapor-deposition⁵³, and magnetron sputtering.⁵⁴ Dip-coating is an economical and facile approach to fabricating nanocoating on a polymer matrix that is easy to scale up with a uniform thickness.⁵²

5.4 Role of waste-derived disinfection agents

Recently, a novel disinfection method has been reported to take advantage of waste oyster shells. A benefit of using oyster shells as a raw material is their abundance. Global oyster yield in 2019 was around 6.1×10^6 tons, and the yield increases yearly.⁵⁵ With the escalating yield, oyster shell waste becomes a greater environmental problem

impacting shorelines and fisheries worldwide. Using waste oyster shells as a disinfectant material would be a win-win strategy, providing a cost-effective material source and alleviating the environmental issue. Research has shown that pulverized oyster and scallop shells heated to over 700 °C exhibit bactericidal activity due to the conversion of calcium carbonate (CaCO_3) to calcium oxide (CaO).^{56, 57} Oikawa et al. (2000) conducted the first study investigating the disinfection efficacy of heated oyster shells against *Staphylococcus aureus* (*S. aureus*), *Escherichia coli* (*E. coli*), and *Pseudomonas aeruginosa*, achieving 0.6-log-inactivation, 0.75-log-inactivation, and 3.8-log-inactivation with 1 g L⁻¹ oyster shell solution in 1 h, respectively.⁵⁸ Later, Sawai *et al.* conducted several studies demonstrating that the heated scallop shells could effectively inactivate *S. aureus* and *E. coli*.⁵⁹

It has been proposed that the disinfection observed with the use of heated oyster shell is related to ROS generation and protein denaturation.⁶⁰⁻⁶⁴ For example, Chen et al. (2015), Sadeghi et al. (2020), and Park et al. (2021) have suggested that the disinfection mechanism of shell-derived disinfectants is related to the generation of HO_2^{\bullet} , $^{\bullet}\text{O}_2$, and H_2O_2 .^{60, 63, 65} In addition, several researchers have reported the presence of HO_2^{\bullet} , $^{\bullet}\text{O}_2$, and H_2O_2 in solutions containing shell-derived disinfectants.^{56, 66-69} However, the presence of $^1\text{O}_2$ has not been reported, and no direct mechanistic evidence has been provided; thus, the disinfection mechanism remains unclear. Nevertheless, knowing how or why a disinfectant deactivates microorganisms is critical for understanding how efficiently the disinfectant removes viable microorganisms. It also provides information towards improvements in the production and efficacy of new disinfectants and the prediction of types of organisms the disinfectant could inactivate.

5.5 Different resistance of gram-positive and gram-negative bacteria towards ROSs

The literature has consistently highlighted the significant health risks posed by food contamination with pathogenic bacteria, such as *S. aureus* and *E. coli*.⁷⁰⁻⁷² *S. aureus* is predominantly associated with food poisoning and is also responsible for severe conditions like toxic shock syndrome, endocarditis, and infections in post-operative wounds. On the other hand, *E. coli*, commonly found in human intestines, is known to cause various infections, including urinary tract infections, cholecystitis, and septicemia. Moreover, *S. aureus* is a gram-positive bacteria, whereas *E. coli* is classified as a gram-negative bacteria. The cell wall of gram-positive bacteria like *S. aureus* is relatively thicker than gram-negative bacteria, measuring 20–80 nm.⁷³ It consists predominantly of a multilayered peptidoglycan structure, accounting for about 90% of its composition. This peptidoglycan forms a dense, three-dimensional lattice due to the glycans being extensively cross-linked. In contrast, the cell wall of gram-negative bacteria such as *E. coli* is thinner, only 10-15 nm, but structurally more complex.⁷⁴ The outer membrane of gram-negative bacteria is primarily composed of lipopolysaccharide (LPS) and includes a few layers of peptidoglycan, approximately 2 nm thick. This outer membrane is characterized by the presence of various lipoproteins, including porins, which are proteins that create pores in the outer membrane.⁷⁵

This distinction in cell wall structure is crucial as it dictates their interaction with ROSs generated in various disinfection processes.⁷⁶ ROSs can damage cellular components due to their oxidative nature, leading to bacterial inactivation. With their outer lipid membrane, gram-negative bacteria can sometimes offer more resistance against ROSs than gram-positive counterparts.²³ This lipid barrier can impede the

penetration of ROSs, necessitating higher ROS concentrations or prolonged exposure for effective disinfection.⁷⁷ This inherent difference in resistance has significant implications for water disinfection strategies.

5.6 Summary

In summary, searching for an ideal disinfectant remains an ongoing and complex challenge. Previous research has underscored the importance of photocatalysis as an effective approach for decomposing organic pollutants and inactivating pathogens, primarily through the generation of ROSs like $^1\text{O}_2$ and $\text{OH}\cdot$. This study will introduce a surface-functionalized, nitrogen-doped TiO_2 -coated polymethyl methacrylate composite (NT-PMMA) created using a dip-coating technique to boost photocatalytic activity through immobilization. It will explore the efficiency of NT-PMMA against both *S. aureus* and *E. coli* under visible light, and compare to the conventional suspension system. Moreover, this study will also investigate the efficacy of an oyster-shell-derived disinfectant against two bacteria, *S. aureus* and *E. coli*, examining its impact on bacterial permeability, morphology, and biophysical properties. The bacterial susceptibility to various disinfectants will be investigated by focusing on *Staphylococcus aureus* and *Escherichia coli* as representative models for gram-positive and gram-negative bacteria. This study will advance our understanding of pathogen inactivation by photocatalyst-immobilized polymers and shell-derived disinfectants, and advocates for applying innovative and environmentally sustainable approaches to pathogen inactivation.

CHAPTER 6

Mode of inactivation of *Staphylococcus aureus* and *Escherichia coli* by heated oyster-shell powder

6.1 Abstract¹

Bacterial infection and subsequent disinfection of microorganisms are ongoing issues around the world. Bio-calcium oxide derived from heated oyster-shell (HOS) waste product has been shown to be an effective disinfectant and has the additional advantage of the marketing use of utilizing waste materials that would otherwise contribute to environmental problems; however, its mode of inactivation is unknown. In this research, fluorescence microscopy (FM), transmission electron microscopy (TEM), atomic force microscopy (AFM), and electron spin resonance (ESR) spectrometer techniques were used to characterize the mode of inactivation of *S. aureus* and *E. coli* via HOS. This is the first work to provide insight into the three-dimensional morphology and biophysical properties of the inactivated *S. aureus* and *E. coli* cells via HOS. Noteworthy, the presence of singlet oxygen in HOS suspension altered bacterial cell permeability, leading to sustained inactivation. The HOS exhibited excellent disinfection capacity and achieved a 5-log-inactivation *E. coli* within 60 min with a dose of 0.2 g/L, superior to other shell-derived disinfectants. Thus, HOS provides a cost-effective disinfectant for the application of controlling pathogens.

Keywords: singlet oxygen, disinfection, heated oyster shell, *Staphylococcus aureus*, *Escherichia coli* singlet oxygen, pathogens

6.2 Introduction

Bacterial infection is a serious issue worldwide [1]. Conventional disinfection methods, including chlorination, UV light, and ozonation, have been well established. However, these methods also have disadvantages, such as the high cost of the raw chemicals, generation of toxic by-products, or low disinfection efficiency [2, 3]. In addition, pathogens develop resistance to traditional disinfectants necessitating the ongoing development of effective disinfectants and promising disinfection methods [4-6]. Recently, a novel disinfection method has been reported that takes advantage of waste oyster shells. A benefit of using oyster shells as a raw material is their abundance. Global oyster yield in 2019 was around 6.1×10^6 tons, and the yield is increasing every year [7, 8]. With the escalating yield, oyster shell waste becomes a greater environmental problem impacting shorelines and fisheries worldwide. Using waste oyster shells as a disinfectant material would be a win-win strategy, providing a cost-effective material source and alleviating the environmental issue.

Research has shown that pulverized oyster and scallop shells heated to over 700 °C exhibit bactericidal activity due to the conversion of calcium carbonate (CaCO_3) to calcium oxide (CaO) [9, 10]. Oikawa et al. (2000) conducted the first study investigating the disinfection efficacy of heated oyster shells against *Staphylococcus aureus* (*S. aureus*), *Escherichia coli* (*E. coli*), and *Pseudomonas aeruginosa*, achieving 0.6-log-inactivation, 0.75-log-inactivation, and 3.8-log-inactivation with 1 g/L oyster shell solution in 1 h, respectively [11]. Later, Sawai et al. conducted several studies

demonstrating that the heated scallop shells could effectively inactivate *S. aureus* and *E. coli* [12].

Advanced oxidation processes (AOP) have gained notice in recent years as effective means for decomposing organic pollutants and inactivating pathogens [13-16]. The procedures rely on the production of highly reactive oxygen-containing species (ROS) such as hydroxide radicals ($\text{OH}\cdot$) and hydrogen peroxide (H_2O_2). These strong oxidants can degrade recalcitrant compounds through reactions involving, for example, Fenton catalysis [17, 18], ozonation [19], and sulfate radical-based reactions [20, 21]. Singlet oxygen ($^1\text{O}_2$) has been reported to be the most reactive ROS, with $94 \text{ kJ mol}^{-1}(\Delta_G H^\circ_{298})$ above the ground state triplet oxygen ($\text{O}_2(^3\Sigma_g^-)$) [22]. Other studies posited that singlet oxygen causes great damage to proteins located on bacterial membranes due to oxidation [23]. Indeed, singlet oxygen demonstrated greater suitability than other ROS as an oxidant for biological targets [24], suggesting that the presence of singlet oxygen is critical in disinfection mechanisms.

It has been proposed that the disinfection observed with the use of heated oyster-shell (HOS) is related to ROS generation and protein denaturation [25-29]. For example, Chen et al. (2015), Sadeghi et al. (2020), and Park et al. (2021) have suggested that the disinfection mechanism of shell-derived disinfectants is related to the generation of $\text{HO}_2\cdot$, $^1\text{O}_2$, and H_2O_2 [25, 28, 30]. In addition, several researchers have reported the presence of $\text{HO}_2\cdot$, $^1\text{O}_2$, and H_2O_2 in solutions containing shell-derived disinfectants [9, 31-34]. However, the presence of singlet oxygen has not been reported, and no direct mechanistic evidence has been provided; thus, the disinfection mechanism remains unclear. Nevertheless, knowing how or why a disinfectant deactivates microorganisms is critical

for understanding how efficiently the disinfectant removes viable microorganisms. It also provides information towards improvements in the production and efficacy of new disinfectants and prediction of types of organisms the disinfectant could inactivate.

Thus, this study aims to elucidate the mechanism by which HOS deactivates two bacteria: gram-positive *S. aureus* and gram-negative *E. coli*. *S. aureus* is one of the primary pathogens involved in nosocomial infections in medical institutions worldwide [35, 36]. *E. coli* is a well-known bioindicator of water and food contamination, inducing diarrhea and even hemolytic uremic syndrome [37, 38]. In this study, we hypothesize that the highly active singlet oxygen generated in the HOS suspension is the primary disinfection mechanism against bacteria. Singlet oxygen further attacks bacterial cells and alters cell permeability, leading to the leakage of cellular components and the collapse of the cell structure. To diagnose the change of biophysical properties in the disinfection process, we used atomic force microscopy (AFM) to characterize the 3D morphology and biophysical properties of inactivated bacteria in the disinfection process, including height, surface roughness, adhesion, and Derjaguin-Muller-Toporov (DMT) elastic modulus. Real-time observation and three-dimensional images of the living bacterial cells provide a better understanding of the disinfection processes. For example, Betancourt et al. (2019) showed the increasing bacterial roughness during sodium hypochlorite inactivation [39], and Pleskova et al. (2016) demonstrated decreasing bacterial height during TiO₂ inactivation [40]. Our research team has exhibited the potential of early diagnosis via AFM for the microbial inactivation processes (Tzeng et al., 2021). To gain insight into the disinfection mechanism, we also monitored cell morphology, cell wall ultrastructure, biophysical properties, and the changes in

intracellular substances (e.g., potassium ions) of the inactivated bacteria. Finally, an electron spin resonance (ESR) spectrometer was employed to identify the active ROS in the HOS suspension.

Thus, this study elaborates on the interaction between HOS and two different bacteria (*S. aureus* and *E. coli*) and the HOS impacts on bacterial permeability, morphology, and biophysical properties. The results increase our understanding of pathogen inactivation by HOS, supporting the application of oyster shell waste as the source of a low-cost, environmentally-friendly disinfectant.

6.3 Materials and Methods

6.3.1 Chemicals

Analytical grade 2,2,6,6-tetramethyl-1-piperidone (TEMP, 95%), furfuryl alcohol (FA, 98%), reagent grade sodium hypochlorite solution (NaClO, 10-15%), propidium iodide (PI), and diamidino-2-phenylindole (DAPI) were purchased from Sigma-Aldrich. 9,10-anthracenediyl-bis(methylene)dimalonic acid (ABDA) was purchased from FLUKA. Difco™ Nutrient Agar was purchased from BD Diagnostics for culturing the bacteria. Uranyl acetate (98-100%) purchased from Spectrum™ and led citrate from Sigma-Aldrich were used for bacterial sample staining.

6.3.2 Preparation and characterization of heated oyster shell (HOS)

Waste oyster shell (*Crassostrea gigas*) was obtained from Wong Gong fishery harbor in Taiwan. Upon reception, the waste shell was washed with tap water to remove surface impurities. It was then soaked in a 1% NaClO solution for 24 h and cleaned with deionized water. The treated shells were oven-dried at 105 °C for 18 h and then

pulverized with a grinder (Rong Tsong Precision Technology Co., RT-N12, Taiwan). The pulverized oyster shell was then heated in a furnace (Cherng Huei, CH-202045, Taiwan) at 105°C for 60 min and calcined by ramping to 1050°C for 120 min. Finally, the calcined powder was cooled to room temperature before grinding in a Planetary Ball Mill (Retsch, PM400, Germany) at 300 rpm for 60 min.

The HOS particle size was analyzed via the dynamic light scattering (DLS) with a Zetasizer (Nano ZS, Malvern, United Kingdom). The specific surface area was obtained by nitrogen adsorption according to the Brunauer-Emmett-Teller (BET) equation (Micromeritics ASAP 2020, USA). The crystal phases of the composites were analyzed by X-ray diffraction (XRD) (BRUKER, D8 SSS, USA) with Cu-K α radiation ($\lambda = 1.54184 \text{ \AA}$), which recorded the data over a 2θ range from 5° to 80°. The surface functional groups were identified using Fourier transform infrared spectroscopy (FTIR 4700, JASCO, Japan) coupled with attenuated total reflection (ATR) over the region 400-4000 cm^{-1} with 4 cm^{-1} spectral resolution.

6.3.3 Detection of generated reactive oxygen species (ROS)

The reactive oxygen species (ROS) were detected using an electron spin resonance (ESR) spectrometer (Bruker, ELEXSYS-II E580 FT/CW system) equipped with an X-band range of 9.49 – 9.88 GHz 8.02 mW power. A 0.05 M 2,2,6,6-tetramethyl-1-piperidone (TEMP, 7.8 mg/mL) solution was used to detect $^1\text{O}_2$ in the aqueous solution. HOS was dispersed in deionized water (1 mg/mL) by ultrasonication for 1 min before adding the trapping agent. The HOS suspension was immediately transferred to the ESR for measurement. The same HOS suspension was then prepared for scavenging experiments, with the addition of furfuryl alcohol (FA) as the scavenger for TEMP- $^1\text{O}_2$.

In order to quantify the yield of singlet oxygen generated from HOS during the disinfection process, 9,10-anthracenediyl-bis(methylene)dimalonic acid (ABDA) was used [41]. A 0.2 mg ABDA was dispersed in 0.1 mL dimethyl sulfoxide (DMSO) to form a 5 mM solution. Then a 5 μ L aliquot of the ABDA solution was added to the 200 μ L HOS suspension (500 ppm). The absorbance at a wavelength of 380 nm at 0 and 120 min was recorded by a microplate reader (Awareness Technology). The whole process was conducted without light exposure.

6.3.4 Disinfection experiments

Staphylococcus aureus (*S. aureus*, ATCC 6538P) and *Escherichia coli* (*E. coli*, ATCC 8739) were purchased from the Bioresource Collection and Research Center, Taiwan. The bacteria strains were cultured on nutrient agar plates for 18 h. The bacteria were washed three times with sterile, deionized water and then re-suspended in 9 mL sterile deionized water. *S. aureus* and *E. coli* were inoculated into polypropylene plastic vessels containing 100 mL sterile water to achieve a desired initial bacterial concentration (10^5 and 10^8 CFU/mL) [42]. The HOS dosage was maintained at 0.2 g/L in the suspension at a pH of 11.5 ± 0.1 . A 0.1 mL bacterial suspension aliquot was from the bulk suspension at different reaction times and cultured on nutrient agar plates using a spread plate method. For comparison, bacterial suspension treated with 100 mL NaOH solution at pH of 11.5 ± 0.1 was prepared. Temperature-controlled (25 $^{\circ}$ C) stirring was maintained throughout the experiments. All agar plates, solutions, glassware, and pipette tips were sterilized in an autoclave at 121 $^{\circ}$ C for 40 min before use in each experiment.

The bacterial survival ratio and disinfection efficiency were calculated as follows:

$$\text{Survival Ratio (\%)} = (N_t / N_0) \times 100 \quad (1)$$

$$\text{Disinfection efficiency (\%)} = (1 - N_t / N_0) \times 100 \quad (2)$$

where N_t and N_0 are bacteria concentrations (CFU/mL) at time t (min) and starting point (0 min), respectively.

6.3.5 Ultrastructure of bacteria and intracellular component leakage

For the transmission electron microscopy (TEM) analyses, the sample was prepared by fixing 5 mL of the bacterial suspensions with 2.5% (v/v) glutaraldehyde for 2 h. The samples were then postfixated with 1% (w/v) osmium tetroxide for 2 h at room temperature. After washing the samples three times with a phosphate buffer (pH 6.8), they were dehydrated in a graded series of ethanol (50%, 70%, 80%, 95%, and 100% v/v) before embedding in 300 μ L LR white resin (London Resin Company Ltd). Next, thin sections of the specimens were cut with a diamond knife. The sectioned samples were double-stained with saturated uranyl acetate and lead citrate [43]. Finally, the grids were examined with a JEM-1400 transmission electron microscope (Hitachi, Tokyo, Japan) at an operating voltage of 12 kV.

To determine potassium ion (K^+) leakage from the bacterial cells during the disinfection process, 10 mL of bacterial suspension was collected at several reaction times: 0, 60, 120, 240, and 360 min. The suspensions were filtered through the 25 mm diameter nylon syringe filters (0.22 μ m pore size, Millipore). After filtration, the K concentrations were measured by inductively coupled plasma optical emission spectrometry (ICP-OES) (Element 2, Thermo Scientific).

6.3.6 Measurement of cell wall permeability via fluorescence microscopy (FM)

To prepare the samples for analysis by FM, a 1-mL aliquot of the reaction suspension was sampled at each of the designed reaction times (0, 60, 120, 240, and 360 min). After the suspension aliquot was centrifuged at $1,000 \times g$ for 5 min, 900 μL of supernatant was removed to get the bacteria pellet. Then, propidium iodide (PI) and diamidino-2-phenylindole (DAPI) were added to the bacteria pellet and mixed for 20 and 40 min, respectively [44]. PI is a red-fluorescent probe that does not permeate cell membranes and is commonly used to detect cell membrane injury. DAPI is a blue fluorescent probe that selectively binds to the minor groove of double-stranded DNA. The samples were analyzed with an inverted fluorescence microscope (IFM) (TH4-100, Olympus, Japan).

For each sample, five different locations were chosen randomly. Two images were taken at each location. The DAPI-stained cells were imaged using a filter with excitation 340-380 nm and suppression at 425 nm. The PI-stained cells were visualized using a filter with excitation at 515 - 560 nm and suppression at 590 nm. Cell counting was conducted with the image processing software (Image J, version 1.53).

$$\text{Membrane permeability ratio (\%)} = (N_{\text{PI}} / N_{\text{DAPI}}) \times 100 \% \quad (3)$$

where N_{PI} is the amount of PI-fluorescent bacteria (CFU), N_{DAPI} is the amount of DAPI-fluorescent bacteria (CFU).

6.3.7 Three-dimensional image and biophysical properties measurement

Following disinfection, the biophysical properties of the inactivated bacteria, including cell height, surface roughness, DMT modulus, and adhesion of the bacterial

surface, were measured by AFM (Dimension Icon, Bruker, USA) in Peak Force QNM mode with ACTA cantilever from AppNano (Applied NanoStructures, Inc., USA). The resonance frequency and spring constant of the ACTA cantilever were 200 - 400 kHz and 25 - 75 Nm⁻¹, respectively. Biophysical properties were measured and analyzed using the instrument-equipped software, NanoScope 6.0. Bacterial surface roughness was calculated from the bacterial surface height using the root-mean-square (R_{rms}) equation Eq. (4).

$$R_{rms} = \sqrt{\frac{\sum_{i=1}^N (Z_i - Z_m)^2}{N-1}} \quad (4)$$

where N is the total number of data points, Z_i is the height of i^{th} point, and Z_m is the mean height [42, 45-48]. The DMT elastic modulus is shown in Eq. (5). DMT model was used when surface deformation was lower than tip radius [49].

$$F_{tip,DMT} = \frac{4}{3} E^* \sqrt{Rd^3} + F_{adh} \quad (5)$$

where F_{tip} is the force on the tip, F_{adh} is the adhesion force, R is the tip radius, d is the sample deformation, and E^* is the equivalent elastic modulus, $E^* = E/(1-\nu^2)$, where ν is the Poisson ratio, and E is the elastic modulus [42, 49]. The bacterial suspension (10 μL) was dropped on the poly-L-lysine coated glass slice and then air-dried for 5 min before conducting AFM scanning.

6.3.8 Statistical analyses

The disinfection experiments and the measurement of cell wall permeability were conducted in triplicate. In addition, the biophysical properties of the bacterial cell were

calculated from ten random points on the bacterial surface using NanoScope 6.0 software. The results mentioned above are presented as mean \pm SD.

6.4 Results and Discussions

6.4.1 Characterizations

HOS has an average particle diameter of $1.8 \pm 0.2 \mu\text{m}$, which is much smaller than that of other shell-derived materials, such as scallop-shell-derived ($30 \mu\text{m}$) [33] and coral-derived ($7.3 \mu\text{m}$) [25] disinfectants. Such size differences likely arise from the preparation processes. As prepared, the HOS has a specific surface area of $7.9 \text{ m}^2 \text{ g}^{-1}$, which is higher than that of other conventional disinfectants, such as ZnO ($4.5 \text{ m}^2 \text{ g}^{-1}$) [50], shown in Table 6-1. The higher surface area and smaller particle size of the HOS enhance disinfection efficiency by providing more active sites in contact with the bacteria.

Table 6-1. Comparison of disinfection performances and approaches for examining disinfection actions to other disinfectants.

Disinfectant	Dose (g/L)	Particle Size (µm)	Surface Area (m ² /g)	Initial Bacterial Concentration (CFU/mL)	Inactivation Performance	Inactivation Method	Approaches for Examining Disinfection Mechanism	References
Oyster shell derived disinfectant	0.2	1.8	7.9	1×10 ⁵	5-log-inactivation in 1h for <i>E. coli</i> ; 3-log-inactivation in 6 h for <i>S. aureus</i>	Suspension	Morphology, biophysical properties, K ⁺ leakage, cell wall permeability, and ROS detection (ESR)	This study

NA: Not available

FTIR analysis of the HOS (Fig. 6-1a) resulted in peaks at 3640 cm^{-1} , 1407 cm^{-1} , and 875 cm^{-1} , which are assigned to the O–H, C–O, and Ca–O bonds, respectively. The characteristic Ca–O bond peak in HOS is consistent with the FTIR spectra of calcined marine coral powders and calcium oxide [25, 51]. Oyster shells contain 95 to 99% calcium carbonate (CaCO_3), which is converted into calcium oxide (CaO) by calcination [32]. The presence of CaO is also supported by the XRD results. The XRD pattern of HOS (Fig. 6-1b) shows major diffraction peaks at 2θ angles of 32.2° , 37.4° , 53.9° , 64.2° , 67.4° , and 79.7° , corresponding to the (111), (200), (220), (311), (222), and (400) crystal faces of CaO (JCPDS Card No. 00-037-1497), respectively. Other minor diffraction peaks at 2θ angles of 18.0° , 28.7° , 34.1° , 47.1° , and 50.8° correspond to Ca(OH)_2 (JCPDS Card No. 00-044-1481). The appearance of Ca(OH)_2 is due to exposure of HOS to moisture in the air [25]. The SEM images (Fig. 6-1c) show that the ground oyster shell particles have a layered structure with a rough surface before heating; whereas, HOS has irregular, almost sintered, and shaped particles (Fig. 6-1d).

6.4.2 Disinfection performance and identifying reactive oxygen species

The efficacy of HOS disinfection was evaluated by comparing the inactivation rate of two different bacterial types: gram-positive bacteria (*S. aureus*) and gram-negative bacteria (*E. coli*). Figs. 6-2a and 6-2b show the inactivation kinetics of the two bacteria observed by culturing the bacterial suspensions in the presence of HOS at different reaction times. As shown in Fig. 6-2a, the survival of *E. coli* decreased dramatically from 1.07×10^5 CFU/mL to 1.40×10^3 CFU/mL after exposure to HOS for 30 min; complete inactivation was achieved within 60 min. In contrast to *E. coli*, a 99.9% inactivation rate was obtained for *S. aureus* only after 360 min. The disparate disinfection efficiency

between *E. coli* and *S. aureus* is related to differences in cell wall structures and the HOS disinfection mechanism. It has been proposed that alkaline condition induced by shell-derived disinfectants was one of the primary factors in the disinfection mechanism. Therefore, we evaluate the effect of alkalinity on bacterial inactivation by using a NaOH solution at the same pH (11.5 ± 0.1) as the HOS suspension. As shown in Fig. 6-2b., there was merely 0.85-log inactivation of *E. coli* and 0.59-log inactivation of *S. aureus* after exposure to NaOH solution for 360 min. The disinfection performance of the NaOH solution against bacteria is much lower than that of the HOS material, which indicates that there is a critical factor in the HOS disinfection mechanism beyond alkalinity. Although previous studies suggested that ROS might be the primary factor in the inactivation mechanism of shell-derived disinfectants, no direct evidence was provided. Herein, we use ESR to verify the presence of ROS species generated in the presence of HOS.

Figure 6-2. (a) HOS disinfection efficiency against *S. aureus* and *E. coli*. Experimental conditions: [HOS] 0.20 g/L, pH= 11.5 ± 0.1, [bacteria] 10⁵ CFU/mL, T = 25 ± 1 °C. (b) NaOH disinfection efficiency against *S. aureus* and *E. coli*. Experimental conditions: pH 11.5 ± 0.1, [bacteria] 10⁵ CFU/mL, T = 25 ± 1 °C. (c) ESR spectra of HOS obtained with TEMP as a spin-trapping agent and furfuryl alcohol (FA) as a quenching agent. Experimental conditions: [HOS] = 1 g/L, [FA] = 0.01 M, T = 25 ± 1 °C. (d) ABDA absorbance reduction at 380 nm of HOS at 0 and 120 min in the dark. Experimental conditions: [HOS] = 500 µg/mL, [ABDA] = 0.005 M, wavelength = 380 nm, T = 25 ± 1 °C.

Generation of ¹O₂ in the HOS suspension was confirmed by ESR using TEMP as a spin-trapped agent. TEMP was selected to trap ¹O₂ and form the stable TEMP-¹O₂ adduct, which can be identified by its typical ESR spectrum with three lines of equal

intensity (aN = 16 G). As shown in Fig. 6-2c, the characteristic 1:1:1 triplet signal of TEMP-¹O₂ adducts was observed, indicating the presence of singlet oxygen in the HOS suspension [54, 55]. To further confirm the formation of singlet oxygen, 0.01 M furfuryl alcohol (FA) was added to the HOS sample to scavenge the singlet oxygen. The intensity of the 1:1:1 peaks of TEMP-¹O₂ adducts was low in the presence of FA, confirming that the singlet oxygen was produced in the system. Moreover, the yield of singlet oxygen was quantified using the ABDA method. A 9,10-anthracenediyl-bis(methylene)dimalonic acid (ABDA) solution has a strong absorption peak at 380 nm, which can be used to detect singlet oxygen generated from HOS. ABDA reacts rapidly with singlet oxygen in the solution, resulting in a decrease in absorbance at 380 nm. As shown in Fig. 6-2d, after ABDA reacting with HOS for 120 min revealed a 21.8% reduction in the absorbance compared with 0 min, which confirmed the generation of singlet oxygen. The methylene blue (MB) at 50 ppm was used as a reference photosensitizer, which showed a 74.8% reduction of absorbance (Fig. B5-3). According to Yu et al. (2015), the quantum yield of singlet oxygen for MB molecules measured by the ABDA method is about 50% under visible light exposure conditions [41]. Compared with the production of light-triggered ¹O₂ via 50 µg/mL MB, the 500 µg/mL HOS exhibited a 14.6% relative yield of singlet oxygen in the dark.

This is the first direct evidence that a ROS species is generated by HOS. Sawai et al. (2001) were the first to speculate that the formation of ROS from scallop shell waste contributed to the inactivation of bacteria; however, they did not identify the ROS species [12]. Since then, other researchers [25, 28, 30] have also suggested that shell waste generated HO₂[•], [•]O₂, and H₂O₂ contributed to its disinfection mechanism. To date, there is

no literature identifying singlet oxygen ($^1\text{O}_2$) in shell-derived disinfectants as a critical component in the disinfection process. Within the ROS, singlet oxygen ($^1\text{O}_2$) has been reported to be the most reactive ROS [22]. The production of $^1\text{O}_2$ using a photocatalyst remains the most popular and efficient method for photo-degradation applications. However, studies of nonphotochemical methods of generating $^1\text{O}_2$ from shell-derived disinfectants are still limited. Bokare & Choi (2015) reported the nonphotochemical generation of $^1\text{O}_2$ using potassium periodate (KIO_4) under alkaline conditions [54]. In addition, Persich et al. (2017) demonstrated the formation of $^1\text{O}_2$ without photolytic irradiation [56]. Moreover, Ikoma et al. (2001) investigated the ROS formation in CaO using ESR, and they proposed that ROSs were generated due to the trapped electrons (e^-) on the surface of CaO. The surface-trapped electrons resulted from the dislocations in the CaO crystal structure in the grinding process. Therefore, the contact between the organic compound and oxygen-rich surface would cause an electron transfer from O^{2-} to the organic substance [57]. The CaO crystal cleavage leads to the point vacancy defects and traps the electrons on its surface. In this study, the formation of $^1\text{O}_2$ in a HOS suspension in the dark was experimentally confirmed using ESR measurements in corroboration with a quenching experiment using furfuryl alcohol as a selective $^1\text{O}_2$ scavenger. The ABDA method also verified about 14.6% relative yield of singlet oxygen formed in HOS suspension in the dark. However, the formation pathway of singlet oxygen needs to be investigated in our future study.

Singlet oxygen ($^1\text{O}_2$) had been reported to react with proteins with a higher rate constant than other biological targets, such as DNA, RNA, and lipids [23, 58]. This feature of singlet oxygen can explain the higher HOS disinfection efficiency against *E.*

coli, which has a high proportion of protein in its cell wall than *S. aureus*. *S. aureus* is gram-positive bacteria with a thick cell wall consisting of peptidoglycan. The thick peptidoglycan layer (20 - 80 nm) could be a barrier to the oxidative disinfection material. In contrast, the structure of the gram-negative bacteria, *E. coli*, is more complex than that of gram-positive bacteria. The outer membrane of *E. coli* consists of lipopolysaccharides (LPS) with porin proteins inserted within them and covers a thin peptidoglycan layer. Although *E. coli* has a multilayer cellular membrane structure, its survival ratio is much lower than that of *S. aureus* with its simple cell wall structure. The differences are attributed to the thickness of the *E. coli* cell wall and the presence of the ROS-denatured proteins on the outer membrane, which may cause the lead to leakage of the intracellular components and cell structure collapse. Therefore, singlet oxygen generation and alkaline conditions induced by HOS result in membrane alteration and bacterial inactivation.

HOS exhibited higher disinfection efficiency against *S. aureus* and *E. coli* than other shell-derived disinfectants. A 5-log-inactivation *E. coli* was achieved within 1 h, and a 3-log-inactivation *S. aureus* was achieved within 6 h with 0.2 g/L HOS (Table 6-1). As shown in Table 6-1, Watanabe et al. (2014) reported a 2-log-inactivation *E. coli* using scallop-shell-derived disinfectant with a dose of 5 g/L [33]; Sawai et al. (2013) indicated a 2-log-inactivation within 1 h against *S. aureus* using scallop-shell-derived disinfectant with a dose of 1 g/L. Moreover, HOS has a higher specific surface area ($7.94 \text{ m}^2/\text{g}$) and smaller particle size ($1.8 \pm 0.2 \text{ }\mu\text{m}$) than other shell-derived disinfectants, which provides more active sites on its surface, further enhancing HOS reaction efficiency and leading to improved disinfection performance.

6.4.3 Damage of bacterial cell wall and leakage of intracellular component

Damage to bacterial cell walls and the loss of bacterial intracellular components in the presence of HOS can be seen in the TEM images (Figs. 6-3 a-h) and plots of changes in K^+ ion concentration over time (Figs. 6-3 i-j), respectively. Before inactivation, the spherically-shaped *S. aureus* and rod-shaped *E. coli* were intact with clear cell walls and uniformly rendered cell interiors. After 120 min, the *S. aureus* cell was still intact (Fig. 6-3b), but the slight aggregation of intracellular components is apparent. By 360 min (Fig. 6-3d), the cell wall was decomposed, damaging the permeability and leading to leakage of the intracellular components. As for *E. coli*, the intracellular components aggregated, and the cell wall ruptured at 120 min (Fig. 6-3f). The blurred boundary and holes in the cell wall (Fig. 6-3g) indicate a damaged cell envelope at 240 min. Additionally, the intracellular components leaked out of the cells due to the change in permeability. Finally, the *E. coli* cell structure collapsed and completely flattened at 360 min (Fig. 6-3h), leaving only cell debris inside. The damaged bacterial ultrastructure observed in the TEM images is in agreement with the leakage of K^+ ions (Figs. 6-3i and 6-3j), which confirm that HOS induced an alteration in bacterial ultrastructure.

Figure 6-3. TEM images of *S. aureus* (a-d) with HOS treatment for (a) 0 min, (b) 120 min, (c) 240 min, and (d) 360 min; *E. coli* (e-h) with HOS treatment for (e) 0 min, (f) 120 min, (g) 240 min, and (h) 360 min. Comparison of the leakage of K⁺ (10⁻⁸ ppm/cell) from (i) *S. aureus* and (j) *E. coli* cells during the treatment of HOS. Experimental conditions: [HOS] = 0.20 g/L, [bacteria] = 10⁸ CFU/mL, T = 25 ± 1 °C.

To further confirm the destruction process of the bacteria, leakage of K⁺ ions was investigated. K⁺ ions are an essential intracellular component. Therefore, the leakage of K⁺ ions was investigated to assess changes in cell permeability throughout the disinfection process. As shown in Figs. 6-3i and 6-3j, K⁺ ion leakage in *S. aureus* increased from 0.10 to 0.35, 0.42, 0.64, and 0.73 10⁻⁸ ppm/cell with increasing reaction times of 60, 120, 240, and 360 min, respectively. As for *E. coli*, K⁺ ion concentrations increased from 0.03 to 0.13 10⁻⁸ ppm/cell after reacting with HOS material for 120 min and stabilizing. Moreover, the different K⁺ concentrations in *S. aureus* and *E. coli* could

be discerned. Grundling (2013) indicated that *S. aureus* maintains a higher K^+ concentration than *E. coli* since *S. aureus* contains two potassium-uptake systems, Ktr and Kdp [59]. Similar results were also reported by Bouhdid et al. (2009), who found a lower K^+ concentration in *Pseudomonas aeruginosa* (gram-negative bacteria) than *S. aureus* (gram-positive bacteria), while *Pseudomonas aeruginosa* was inactivated more quickly than *S. aureus* by *origanum compactum* essential oil [60].

The oxidative stress and alkaline conditions produced by shell-derived disinfectants would also alter bacterial metabolism, damage cell permeability, and impact cell structure. The unstable cell permeability would in turn lead to leakage of extracellular components, such as K^+ ions. K^+ ions participate in regulating polysome content and protein synthesis of bacterial cells [61-63]. Imbalances of K^+ ion in bacterial cells would then affect cell viability, resulting in cell dysfunction or death [61, 64, 65]. Therefore, the results in TEM images and K^+ ion leakage suggested that the cell wall and cell permeability have been damaged, thus leading to the inactivation of *S. aureus* and *E. coli*.

6.4.4 Cell wall permeability methods and comparison of inactivation

Permeability of the cell membrane is another indispensable indicator diagnosing the damage level over bacteria. In this work, the cell membrane permeability measurements were conducted by using an inverted fluorescence microscope (IFM). Propidium iodide (PI) and diamidino-2-phenylindole (DAPI) were used to distinguish intact bacteria from those with permeated cell membranes [66]. DAPI can pass through an intact cell membrane and bind to bacterial DNA, giving off a blue fluorescence. PI cannot pass through an intact cell membrane and can only bind with the DNA if the cell

membrane is damaged [67]. Experimentally, the blue fluorescence of DAPI will be detected in all the cells; whereas, the red fluorescence of PI will only be displayed in the permeated cells. Figs. 6-4a and 6-4e show that the intact cells of *S. aureus* and *E. coli* appeared with the blue fluorescence and no red fluorescence at 0 min. As seen in Figs. 6-4b and 6-4f, the red fluorescence rises over time as the cell membranes of *S. aureus* and *E. coli* are gradually altered with reaction time. The amount of red fluorescence stabilized within 240-360 min. Interestingly, the DAPI/PI double-stain results reveal that the cell membrane of *S. aureus* are permeable at 120 min, while the plate-counting results show the 92.5 % of the bacteria are still viable at that time. A general consensus is that the conventional agar plate method for counting the culturable bacteria includes different levels of damage to cell membranes [66, 68, 69]. Nevertheless, the degree of permeability damage to a cell membrane ought to be quantified to understand the physiological state of the bacterium. In this study, viable bacteria were counted at different reaction times by the plate counting method. Then, FM imaging was used to distinguish bacteria with intact cell membranes from those with permeated cell walls. The number of blue fluorescent bacteria indicated total bacteria because DAPI can be transmitted through both intact and damaged cell membranes. The number of red fluorescent bacteria indicated those with damaged or permeable cell membranes. The inactivation rates of the bacteria estimated by the two different methods, the plate counting method and the DAPI/PI double-stained method, were compared.

Figure 6-4. FM images of *S. aureus* (a-d) with HOS treatment for (a) 0 min, (b) 120 min, (c) 240 min, and (d) 360 min; *E. coli* (e-h) with HOS treatment for (e) 0 min, (f) 120 min, (g) 240 min, and (h) 360 min. Inactivation ratio of (i) *S. aureus* and (j) *E. coli* measured by two methods with HOS treatment. Experimental conditions: [HOS] = 0.20 g/L, [bacteria] = 10^8 CFU/mL, $T = 25 \pm 1$ °C.

As shown in Figs. 6-4i and 6-4j, the cell-wall-permeability measurement and the percentage of viable bacteria determined with the agar plates showed that the number of red fluorescent bacteria did not correspond to the number of inactivated bacteria. This phenomenon occurred predominantly when determining the cell-membrane-permeability ratio of *S. aureus* (Fig. 6-4i) early in the course of the experiment. The cell-membrane-permeability measurements showed that the permeability of *S. aureus* was altered within

60 min of the reaction and by 120 min, its permeability ratio (red/blue fluorescence) had increased to 44.2%, while its inactivation rate (counting-plate method) remained at 7.5%. This indicates that changes in the permeability of *S. aureus* that appear in the early stages of the reaction, likely due to attack by singlet oxygen and the alkaline conditions, do not lead to the immediate death of *S. aureus*. On the other hand, the *E. coli* permeability ratio had risen to 62.5% by 120 min while its inactivation rate reached 99.3% within the same timeframe. These differences between the permeability ratios and inactivation rates of *S. aureus* and *E. coli* suggest that different inactivation phenomena occur between gram-positive and gram-negative bacteria. Exposure to the HOS quickly induced damage in *E. coli* cell permeability and structure, resulting in the leakage of intracellular components, including DNA. The DNA could then be decomposed by ROS and, therefore, was unable to bind with the PI dye, leading to the slow increase in the inactivation ratio quantified by the cell-membrane-permeability measurement. Thus the disparity between the results obtained using the two methods used to assess inactivation (inactivation ratio vs. permeability ratio) can provide insight into not only the mode of inactivation but also the definition of inactivation.

6.4.5 Biophysical properties of the bacterial cell

AFM is an outstanding technique for measuring live cells with various biophysical properties and imaging real-time disinfection processes. To understand the disinfection mechanism of HOS, the three-dimensional morphology and the biophysical properties of bacteria were investigated by using AFM. The bacterial cells were observed in hydrated conditions without any sample pretreatment, such as staining or dehydration. AFM three-dimensional images of both *S. aureus* (Fig. 6-5a) and *E. coli* (Fig. 6-5e)

showed the spherically-shaped and rod-shaped bacteria at 0 min, respectively. After contact with HOS for 240 min, *S. aureus* remained relatively intact until a minor collapse appeared in the cell wall at 360 min. In contrast to *S. aureus*, the ruffled bacterial surface of *E. coli* appeared intact after reacting for 120 min, before structure collapse occurred at 240 min. The formation of vesicle-like structures on the bacterial surface was evident at 360 min. Thus, the three-dimensional AFM images offer valuable morphological information about *S. aureus* and *E. coli* during the disinfection process that surpasses the two-dimensional limitations of conventional methods, such as SEM. The AFM images in Fig. 6-5h depict the striking effect of decomposition on the *E. coli* cell wall structure. In contrast, there is merely minor damage to the structure of *S. aureus*.

Figure 6-5. Comparison of the three-dimensional morphology of *S. aureus* (a-d) with HOS treatment for (a) 0 min, (b) 120 min, (c) 240 min, and (d) 360 min; *E. coli* (e-h) with HOS treatment for (e) 0 min, (f) 120 min, (g) 240 min, and (h) 360 min. Biophysical properties of *S. aureus* and *E. coli* with HOS treatment, including (i) height, (j) surface roughness, (k) DMT modulus, and (l) adhesion. Experimental conditions: [HOS] 0.20 g/L, [bacteria] 10^8 CFU/mL, $T = 25 \pm 1$ °C.

To further analyze the cell wall biophysical properties, bacterial height, surface roughness, DMT modulus, and adhesion were described by the root-mean-square value obtained from AFM force measurements. As shown in Figs. 6-5 (i-1), when *S. aureus* reacted with HOS material for 120, 240, and 360 min, the bacterial cell height gradually dropped from 568.9 ± 15.6 nm to 342.2 ± 40.3 nm. The roughness of the *S. aureus* cell surface increased slightly from 1.34 ± 0.42 nm to 1.66 ± 0.51 nm, DMT modulus dropped from $2,223.0 \pm 623.7$ MPa to 394.1 ± 154.5 MPa, and adhesion increased from 1.15 ± 0.40 nN to 1.38 ± 0.59 nN. After reacting with HOS material for 120, 240, and 360 min, the *E. coli* bacterial height decreased from 150.4 ± 8.3 nm to 105.5 ± 29.1 nm. The surface roughness increased from 0.95 ± 0.21 nm to 4.46 ± 0.34 nm, DMT modulus dropped from $2,492.2 \pm 1202.9$ MPa to 866.9 ± 337.8 MPa, while the adhesion increased from 1.48 ± 0.34 nN to 3.10 ± 1.42 nN. According to the results, the alteration to the surface roughness, DMT modulus, and adhesion was time-dependent. Changes in the *S. aureus* and *E. coli* cell heights occurred due to the loss of intracellular components. The height of *S. aureus* dropped by 39.8%, whereas *E. coli* heights dropped by 29.8% as compared to the cell heights at time 0. The extensive destruction of the cell wall was also reflected in an increase in the surface roughness of the cells. The measured roughness of *S. aureus* and *E. coli* increased as much as 23.6% and 370%, respectively.

Alteration of the cell envelope composition of *S. aureus* and *E. coli* also resulted in a decreased elastic modulus. The DMT model is one of the elastic modulus models that reflected the contact and deformation between the AFM probe and the sample. Mathelie-Guinlet et al. (2020) revealed a decreased modulus value of treated *E. coli* cell, representing the softening *E. coli* cell envelope due to the lack of lipoprotein Lpp in the

outer membrane [70]. Moreover, Jin et al. (2010) reported that the photo-inactivated *S. aureus* and *E. coli* treated by hematoporphyrin monomethyl ether possessed lower modulus values indicating the cell envelope composition had changed [71]. Similarly, the decreased DMT modulus of *S. aureus* and *E. coli* after being treated with HOS indicated the reduced stiffness of the cell envelope. Furthermore, the HOS-treated cell exhibited increasing adhesion force with the increasing reaction time. Adhesion of the bacterial cell surface, measured by AFM, results from the interaction between the probe tip and cell surface. It indicates that the probe tip interacted with the HOS-treated cell wall components more strongly than untreated cells. The permeated cell membrane and leakage of the intracellular components revealed that the chemical composition of the cell surfaces changed during the disinfection process. Therefore, the AFM probe-tip might have penetrated the decomposed cell wall and interacted with the peptidoglycan or lipopolysaccharide layer of the gram-positive and gram-negative bacteria, leading to the observed increase in the adhesion force [46].

6.4.6 Discrepancy disinfection efficiency between gram-positive and gram-negative bacteria

In view of the discrepancies between disinfection efficiencies reported in the literature in Table 1, it is necessary to adopt multiple approaches to investigate disinfection effects on bacteria, such as determining the changes in morphology, ultrastructure, cell permeability, and biophysical properties of the bacterium. The ultrastructure (TEM images) and three-dimensional (AFM images) micrographs show that *S. aureus* retains its spherical form throughout the disinfection process; whereas, rupture, alteration, and loss of cell wall structure are observed in *E. coli*. However,

leakage of essential potassium ions was detected in *S. aureus* at a higher rate than in *E. coli*. The FM images confirm the changes in the cell membranes, with a higher ratio of permeated cell membranes with *S. aureus* than inactivated cells measured by the plate-counting method. The cell ultrastructure obtained by TEM also indicated the loss of intracellular components in *S. aureus* after reacting with HOS for 360 min. By comparison, the cell envelope of *E. coli* was clearly damaged by 120 min. The *E. coli* cell membrane was decomposed with compromised permeability leading to the loss of intracellular components, such as potassium ions. The mechanical properties of the bacteria mainly consist of the cell membrane and the turgor pressure of the cell. The permeated cell membrane and leakage of the intracellular components affected the turgor pressure of the bacterium and cell growth [72].

The cell-membrane-permeability measurements show that there are significant differences between gram-positive and gram-negative bacteria due to their cell structures (Fig. 6-6). The cell wall of gram-positive bacteria is thick (20 - 80 nm) and composed of multilayered peptidoglycan (90%). The glycans are cross-linked to one another, forming a three-dimensional lattice. On the other hand, the cell wall of gram-negative bacteria is thinner (10-15 nm) but more complicated than that of gram-positive bacteria. The outer membrane (OM) is composed primarily of lipopolysaccharide (LPS) and a few layers of peptidoglycan (around 2 nm thick). The OM also contains many lipoproteins, including porins proteins that form pores in the outer membrane. Even though LPSs form a permeability barrier, the outer membrane is more permeable than the plasma membrane due to the presence of tube-shaped porin proteins in the outer membrane [73]. The disrupted outer membrane porins (OMPs) enhance cell lysis due to increased ROS levels

[74]. Furthermore, $^1\text{O}_2$ has been reported to damage the dominant and side chains of amino acids, peptides, and proteins [23, 58]. Therefore, the generation of singlet oxygen in HOS suspensions results in higher disinfection efficiency against *E. coli* than *S. aureus*. Or, in other words, *S. aureus* displays greater resistance to HOS due to its thick peptidoglycan layer and lower protein content in its cell wall [2].

Figure 6-6. Schematic illustration of the disinfection mechanism of *S. aureus* (*Gram-positive*) and *E. coli* (*Gram-negative*) treated with HOS.

6.5 Conclusions

The HOS displayed high disinfection efficiency toward *E. coli* and *S. aureus*, achieving 99% inactivation in 30 min and 360 min, respectively. The different cell structures led to disparate disinfection efficiency rates between gram-positive and gram-negative bacteria. This study provides a template for the early assessment of altered bacterial cell structure and cell membrane permeability using FM, TEM, and quantification of K⁺ that leaks from bacterial cells. The biophysical properties have

shown the damage to bacterial height, surface roughness, DMT modulus, and adhesion following HOS treatment. The three-dimensional AFM images also revealed the greater vulnerability of *E. coli* cellular structure relative to *S. aureus*. The findings provide evidence that cell permeability is crucial in the HOS disinfection process and that cell wall structure results in different levels of cell permeability damage between *S. aureus* and *E. coli*. Furthermore, analysis of the ROS induced by HOS treatment revealed that singlet oxygen plays an essential role in the disinfection mechanism. Overall, the HOS disinfectant, derived from natural resources, has the high potential to be applied as a universal disinfectant, as well as alleviating an aquaculture waste pollution problem.

CHAPTER 7

Substantial improvement in photocatalysis performance of N-TiO₂ immobilized on PMMA: Exemplified by inactivation of *Staphylococcus aureus* and *Escherichia coli*

7.1 Abstract²

Photocatalysis is an efficient process for degrading organic pollutants and inactivating pathogenic microorganisms. However, this process constantly suffers from turbidity shading and particle aggregation in a catalyst suspension system, thereby reducing its photocatalytic activity. Immobilizing the photocatalyst on the light-transmissible surface is a viable solution to the obstacles. So far, the photo-inactivation efficacy between the immobilized photocatalyst and suspension systems has yet to be compared and investigated. In this study, N-TiO₂ (NT) immobilized on poly-methyl-methacrylate (PMMA) was fabricated via a dip-coating method, which has a high transmittance rate of 92% - better than all of the previous works (50%). By immobilizing N-TiO₂ on PMMA, up to 60% and 19% improvements in inactivation efficiencies against Gram-positive *Staphylococcus aureus* (*S. aureus*) and Gram-negative *Escherichia coli* (*E. coli*) are achieved, respectively, relative to a photocatalyst suspension. Notably, reactive oxygen species (ROSs) detection results indicate that 5 g L⁻¹ NT coated PMMA ((NT-PMMA)₅) has higher intensities of singlet oxygen (¹O₂), hydroxyl radicals (HO[•]), and higher concentration of hydrogen peroxide (H₂O₂) than the NT suspension. The as-made NT-PMMA sustains a 99.99% inactivation efficiency (5-log-inactivation) against *S. aureus*

² Yen, L.-T., Weng, C.-H., Tzeng, J.-H., Chen, Y.-C., Jacobson, A. R., & Lin, Y.-T. (2024). Substantial improvement in photocatalysis performance of N-TiO₂ immobilized on PMMA: Exemplified by inactivation of *Staphylococcus aureus* and *Escherichia coli*. *Separation and Purification Technology*, 345, 127298.

through five consecutive photocatalysis cycles of reuse. The inactivation kinetics of *S. aureus* and *E. coli* fit well with the modified Hom model. Atomic force microscopy observations indicate that the NT-PMMA inactivation causes more severe damage to *S. aureus*'s cell wall than *E. coli* due to the different susceptibility of cell wall structure to ROSs. This study paves a substantial way for scaling up the immobilizing catalyst on PMMA for the effective photocatalytic inactivation of pathogens under visible light.

Keywords: N-TiO₂, poly-methyl-methacrylate, hydrogen peroxide, hydroxyl radicals, immobilization, photocatalysis, singlet oxygen

7.2 Introduction

Chlorination, ozonation, and ultraviolet (UV) light are conventional techniques used to inactivate pathogenetic bacteria in water and wastewater treatment processes. However, they still have drawbacks, such as high operating costs and inadequate inactivation performance. Photocatalysis has the potential to serve as an alternative technology due to its emerging ability to degrade persistent organic pollutants and inactivate pathogens effectively (Tzeng et al., 2021; Yen et al., 2022). because of its large band gap, titanium dioxide (TiO₂), one of the most popular photocatalysts, can only be activated under radiation with wavelengths below 350 nm. Element doping of TiO₂, for example, nitrogen and carbon, can further narrow the bandgap, allowing it to utilize the full spectrum of visible light in sunlight for photocatalysis.

Photocatalysts have typically been used in suspension systems for photooxidation. However, such a TiO₂ suspension process often suffers from the adverse effects of particle aggregation and turbidity shading in the catalyst suspension, thereby reducing its

photocatalytic activity. Immobilizing photocatalysts on a surface offers a solution system to minimize such effects (Terra et al., 2023). The immobilization of photocatalysts by fixing the catalyst powder to a support material provides a long-term and cost-effective inactivation solution without additional post-treatment steps, thereby minimizing overall operational expenses (Goutham et al., 2019). Furthermore, the immobilized photocatalyst allows readily reusing immobilized photocatalysts without recovery or separation from suspension, thereby reducing ecotoxicity concerns (Wood et al., 2020; Zhang et al., 2023). Previous studies have shown that immobilized TiO₂ is capable of bacteria inactivation. Cantarella et al. (2016) embedded TiO₂ in polymethyl methacrylate (PMMA) with a dose of 150 g L⁻¹. They found 4.8-log inactivation of *E. coli* in 1 h under UV light irradiation. Varnagiris et al. (2021) immobilized carbon-doped TiO₂ on the surface of high-density polyethylene (HDPE) beads, which resulted in a 2.5-log photocatalytic inactivation of *Salmonella typhimurium* in 1 h under UV light irradiation (5 mW cm⁻²). So far, the inactivation efficiency of immobilized photocatalysts against bacteria under visible light irradiation and the comparison with the suspension system have yet to be explored.

Poly-methyl-methacrylate (PMMA) has excellent impact strength, UV resistance, and high transparency to visible light and is the most frequently used commercial polymer in architecture, electronics, and furniture (El-Newehy et al., 2022; Khaled et al., 2007). By sprinkling a layer of TiO₂ on PMMA fabricating a TiO₂/PMMA film, Ounas et al. (2020) showed that the photocatalytic degradation of methylene blue with UV light irradiation remained merely only 60% after 250 min because the sprinkling method reduced PMMA light transmittance by 50%. To improve the light transmittance, other researchers have adopted methods to functionalize the PMMA polymer matrix with the minimum influence

on its original properties, including dip-coating (Wu et al., 2022), vapor-deposition (Peng et al., 2022), and magnetron sputtering (Hao et al., 2022). Dip-coating is an economical and facile approach to fabricating nanocoating on a polymer matrix that is easy to scale up with a uniform thickness (Wu et al., 2022). However, an immobilized catalyst with high transmittance properties responsive to visible light is still needed. So far, studies have yet to successfully immobilize photocatalysts, maintain ultra-transmittance, and evaluate the bacterial inactivation efficiency under visible light.

This study fabricated a high transmittance, surface-functionalized TiO₂-coated PMMA composite (NT-PMMA) using a dip-coating technique to enhance photocatalytic activity via immobilization. For the first time, the inactivation efficiency of NT immobilized PMMA composite against gram-positive *S. aureus* and gram-negative *E. coli* bacteria was explored under visible light. The test adopted two bacterial strains due to their different cell structures and varying susceptibility to photooxidation reactions. Noteworthy, a comparison of inactivation efficiency and the reactive oxygen species (ROSs) intensity between immobilized NT-TiO₂ and NT-TiO₂ suspension was investigated in this study. A modified Hom (MH) inactivation kinetic model was used to simulate the inactivation process and determine the light intensity and NT-PMMA dose effects on photocatalytic inactivation. The durability of the photocatalysts was evaluated by subjecting the NT-PMMA to five cycles of photoinactivation reaction. Lastly, the early changes in the biophysical properties of inactivated *S. aureus* and *E. coli* strains were observed using atomic force microscopy (AFM) analysis. This study provides insight into pathogen inactivation by NT-PMMA and supports the application of a photocatalyst-immobilized polymer as an environmentally friendly inactivation approach.

7.3 Materials and Methods

7.3.1 Chemicals

Small sheets of PMMA (5 cm × 5 cm × 0.5 cm) were obtained from Tzy Feng Tech Co. Ltd, Taiwan. Strains of *S. aureus* (ATCC 6538P) and *E. coli* (ATCC 8739) were obtained from the Bioresource Collection and Research Center in Taiwan. Reagent grade ethanol (99.9%), ammonium hydroxide (28-30%), and titanium isopropoxide (97%) were purchased from J.T. Baker (United States) and Invitrogen (United States), respectively.

7.3.2 Preparation of NT-PMMA

NT was synthesized using a modified sol-gel method, as described by Lin et al. (2015). In brief, a triple-necked round bottom flask was filled with 200 mL of ethanol, followed by 50 mL of deionized water and 150 mL of ammonium hydroxide. The solution was stirred at 350 rpm and placed in a low-temperature thermostatic water bath to maintain the temperature at 4 °C. Over a period of 4 min, 10 mL of titanium tetra-isopropoxide was added dropwise, and stirring was continued for 4 h. The solution was left to stir overnight, after which the solid particles were allowed to settle, and the supernatant was decanted. The resulting precipitate was washed twice with distilled water, dried in an oven at 105 °C overnight, and then calcined in a vacuum furnace for 1 h at 500 °C.

NT-coating solutions were prepared by mixing NT powder with isobutyl alcohol (99%, Sigma-Aldrich) at concentrations of 0.1, 0.75, 1, 2.5, 5, 10, and 20 g L⁻¹. The solutions were ultrasonicated at 40 kHz for 10 min before use. NT was coated onto the

PMMA surface using a dip coater (Bungard, RCD15, Germany). To ensure that the thickness of NT on the PMMA surface was coated uniformly, the dipping speed was fixed at 1.2 cm min^{-1} for 5 sec in the NT coating solution, and then the PMMA was pulled up at a stable speed of 1.2 cm min^{-1} . NT-PMMA was dried in an oven at $80 \text{ }^\circ\text{C}$ for 2 min and stored in a clean petri dish ready for use. The light transmittance of NT-PMMA was measured using a full-spectrum transmittance measuring instrument (Rainbow light, TSM-02, Taiwan) following ASTM standards (ASTM D1003-13). The analysis was performed first with plain PMMA as a reference, followed by the $0.1\text{-}20 \text{ g L}^{-1}$ NT-PMMA.

7.3.3 Characteristics of NT and NT-PMMA

The X-ray Diffraction (XRD) measurements of the NT-PMMA composite were carried out using a BRUKER D8 SSS instrument (USA) with $\text{Cu-K}\alpha$ radiation to determine its phase composition and crystallite size. Dynamic Light Scattering (DLS) with a Zetasizer (Malvern, U.K.) was used to analyze the particle size. The optical absorption response of the composite was measured with a UV-Vis spectrometer (Hitachi, Japan) equipped with an integrated sphere, with BaSO_4 as a reference. The specific surface area was determined using the Brunauer-Emmett-Teller (BET) method on a Micromeritics ASAP 2020 instrument (USA). The morphology of NT on the PMMA surface was observed with a scanning electron microscope (JEOL, Japan). The transmittance of the NT-PMMA was measured by full spectrum transmittance using a transmittance measuring equipment (TSM-02; Rainbow Light Technology, Taiwan), following the standard method ASTM D 1003. The methods for photoelectrochemical characterization, including electrochemical impedance spectroscopy (EIS), transient

photocurrent (TPC), photoluminescence spectroscopy (PL), and UV–vis diffuses reflectance spectra were shown in Supplemental Information (text S1).

7.3.4 Detection of generated ROSs

Reactive oxygen species (ROSs) were identified using an electron spin resonance (ESR) spectrometer (Bruker, USA) operating within the X-band frequency range of 9.49 – 9.88 GHz with an output power of 8.02 mW. For the detection of singlet oxygen ($^1\text{O}_2$), a 0.05 M solution of 2,2,6,6-tetramethylpiperidine (TEMP) was employed, while a 0.05 M solution of 5,5-dimethyl-1-pyrroline N-oxide (DMPO) was used to identify hydroxyl radicals (HO^\bullet) and superoxide ions ($\text{O}_2^{\bullet-}$) in the aqueous solution. One mL NT suspension and (NT-PMMA)₅ reaction suspension were immediately transferred to the measuring cuvette, respectively. Another 1 mL trapping agent was added directly to the cuvette before the ESR measurement. The same suspensions were employed for scavenging experiments, with the inclusion of 0.01 M furfuryl alcohol (FA) as the scavenger for TEMP– $^1\text{O}_2$, 0.01 M tert-butanol (TBA) as the scavenger for DMPO– HO^\bullet , and 0.01 M p-benzoquinone (BQ) as the scavenger for DMPO– $\text{O}_2^{\bullet-}$. The production of H_2O_2 was quantified using a triiodide method. Detailed procedures for this analysis is illustrated in the literature (Diesen & Jonsson, 2014).

7.3.5 Inactivation Efficacy of NT-PMMA

This study employed the ISO 22196 standard method to measure the antibacterial activity on non-porous surfaces. Prior to the experiment, *E. coli* and *S. aureus* were cultured on nutrient agar for 18 h at 37 °C, resulting in a bacterial suspension of 10^5 CFU mL⁻¹ obtained by mixing bacteria with 1/500 NB (*E. coli*) or 1/500 TSB (*S. aureus*). The 0.4 mL

bacterial suspension was then dropped onto the surface of NT-PMMA, which was covered with a sterilized polyethylene cover film ($5 \times 5 \text{ cm}^2$) and kept at a controlled humidity by adding 1 mL of deionized water on a cotton pad. Visible light irradiation was conducted in a reaction box equipped with fluorescent lamps (T5 8W 6000 K, Kanjin, Taiwan), with light intensity ranging from $0.24\text{--}1.74 \text{ mW cm}^{-2}$. The samples were exposed to visible light for 0, 30, 60, 180, 360, 720, 900, 1080, and 1440 min. After exposure, the bacterial cells on the surface of NT-PMMA and the polyethylene cover film were flushed with 10 mL of soya casein digest lecithin polysorbate broth (SCDLP), and 1 mL of the SCDLP bacterial suspension was serially diluted and cultured on nutrient agar for 18 h at $37 \text{ }^\circ\text{C}$.

A comparison was conducted to assess the inactivation efficiencies between immobilized NT-PMMA and NT suspension. *S. aureus* and *E. coli* were cultured on nutrient agar plates for 18 h. After rinsing three times with sterilized deionized water, the bacterial pellets were resuspended in 9 mL of sterilized deionized water. Then, 100 mL of sterilized water was added to polypropylene plastic vessels, and the bacterial strains were inoculated to achieve an initial bacterial concentration of 10^5 CFU mL^{-1} . Subsequently, 0.5 g NT was added. The suspension was exposed to visible light with an intensity of 0.54 mW cm^{-2} . At increasing reaction intervals (0, 60, 180, 360, 720, and 1440 min), bacterial suspension with volume of 0.1 mL was serial-diluted and cultured on agar plates. The bacterial survival ratio and inactivation efficiency were calculated using the following formulas:

$$\text{Survival ratio (\%)} = (N_t / N_0) \times 100 \quad (1)$$

$$\text{Inactivation efficiency (\%)} = (1 - N_t / N_0) \times 100 \quad (2)$$

where N_t represents the bacterial concentration (CFU mL⁻¹) at time t (min); N_0 represents the bacterial concentration (CFU mL⁻¹) at the starting point (0 min).

The durability of the photocatalysts was evaluated by subjecting them to five cycles. After each cycle, NT-PMMA was washed several times with ethanol and water to eliminate residual organic compounds produced from the degradation of bacteria. The NT-PMMA was then dried at 80 °C, irradiated by UV light for 2 h to remove the residual organic compound on the surface, and reused for four subsequent tests.

7.3.6 Inactivation kinetic model

The MH model is utilized for analyzing the kinetics of photocatalytic bacterial inactivation processes. The model fitting involves simulating inactivation profiles with three independent rate constants corresponding to a shoulder region, log-linear region, and final tail inactivation (Ganguly et al., 2018; Yemmireddy & Hung, 2015). The MH model has been successfully used for describing bacterial inactivation kinetics by double-layer ZnO/Al₂O₃ thin film (Meznaric et al., 2022) and spinel ferrite CuFe₂O₄ (Ozkal, 2022) nanocomposites. The three rate constants illustrate three inactivation phases in a photocatalytic process, i.e., accumulation of ROSs in the surrounding bacteria, rapid log-linear bacterial inactivation due to the ROSs attack, and the deceleration of cell damage.

$$\log \frac{N_t}{N_0} = -k_1[1 - \exp(-k_2 t)]^{k_3} \quad (3)$$

where k_1 , k_2 , and k_3 are the empirical rate constants corresponding to shoulder, log-linear reduction, and tailing distinct regions; $\log(N_t/N_0)$ is the bacterial log reduction unit, N_t is the bacterial population at the time (t), and N_0 is the initial bacterial concentration. The

KaleidaGraph 4.0 software was used to fit the experimental data to the MH model. The accuracy of the model's quantitative predictions was assessed using the root mean square error (RMSE), as shown in Eq. (4).

$$RMSE = \sqrt{\frac{\sum \left[\left(\log \frac{C}{C_0} \right)_{pred} - \left(\log \frac{C}{C_0} \right)_{exp} \right]^2}{n}} \quad (4)$$

7.3.7 Identifying the biophysical properties of the damaged bacteria

The inactivated bacteria's biophysical properties were measured using AFM in Peak Force Quantitative Nanomechanical Mapping (QNM) mode after being exposed to visible light irradiation on NT-PMMA. The measurement was conducted using an ACTA cantilever with a resonance frequency of 200–400 kHz and a spring constant of 25–75 Nm^{-1} . The equipment used for the measurement was Dimension Icon from Bruker in the USA, and the cantilever was from AppNano in the USA. To conduct the AFM scanning, a bacterial suspension of 10 μL was dropped on a sheet of glass coated with poly-L-lysine and air-dried for 5 min. The photo-inactivation experiments were repeated three times. The biophysical characteristics of bacterial cells were determined by analyzing ten distinct locations on the bacterial surface with NanoScope 6.0 software. The roughness of the bacterial surface was assessed by root-mean-square (R_{rms}) (Eq. 5) (Girasole et al., 2007; Tzeng et al., 2020).

$$R_{rms} = \sqrt{\sum_{i=1}^N \frac{(Z_i - Z_m)^2}{N-1}} \quad (5)$$

where N stands for the total number of data points, Z_i represents the height of the i^{th} point, and Z_m signifies the mean height.

7.4 Results and Discussions

7.4.1 Characterization of N-TiO₂

Table B6-1 summarizes the characterization results of NT. XRD analysis confirmed that NT was 100% anatase phase, with significant diffraction peaks observed at 2θ angles of 25.5° , 38.0° , 48.2° , 54.5° , 55.3° , and 63.06° , corresponding to the (101), (104), (200), (105), (211), and (204) planes, respectively (Fig. S7-1). The anatase phase of TiO₂ has been found to be the most effective for generating ROSs (Joost et al., 2015). The crystallite size of NT was determined to be 37 nm using the Scherrer formula. The specific surface area of NT is $45.3 \text{ m}^2/\text{g}$, with a pore size of 6.9 nm and a pore volume of $0.13 \text{ cm}^3/\text{g}$. The bandgap energy of NT, calculated from the plot of $(\alpha h\nu)^{1/2}$ versus photon energy, was found to be 2.4 eV (Lin et al., 2015). The nitrogen dopant in TiO₂ lowered the bandgap from 3.2 eV (pure anatase TiO₂) to 2.4 eV, making NT more photoactive under visible light irradiation. The photoelectrochemical characterization, including electrochemical impedance spectroscopy (EIS), transient photocurrent (TPC), photoluminescence spectroscopy (PL), and UV–vis diffuses reflectance spectra for NT used in this study were shown in Figs. B6-2, B6-3, S8-4, and B6-5. NT showed an absorption threshold at approximately 415 nm (Fig. B6-2). As shown in Fig. B6-3, NT has a smaller radius compared to the pure anatase TiO₂, suggesting the electron transfer process of NT is faster.

7.4.2 Transmittance measurement of NT-PMMA

PMMA is widely used in commercial products due to its excellent light transmittance feature with potential as an alternative to glass. It is important to determine

whether the coating of NT onto PMMA would affect light transmittance. As shown in the SEM images (Figs. 7-1a and 7-1b), the dip-coated NT particles are uniformly distributed on the PMMA surfaces with minimal aggregation. PMMA without coating exhibited a transmittance of 94%, while PMMA coated with NT suspensions still maintained high transmittances of 93-88% in the NT coating concentration ranging from 0.1 g L⁻¹ to 20 g L⁻¹ (Fig. 8-1c). These transmittances of NT-PMMA are far superior to the 50% transmittance obtained using the sprinkle method (Ounas et al., 2020). No noticeable screening effect of the NT coating of NT-PMMA was detected (Fig. 7-1d). The excellent transmittance results suggest that PMMA is a promising substitute for glass for coating NT.

Figure 7-1. SEM images of (NT-PMMA)₅ with resolutions of (a) $\times 10,000$ and (b) $\times 80,000$. (c) Effect of NT coating concentration on the transmittance of NT-PMMA and (d) NT-PMMA transmission images.

7.4.3 Comparison of inactivation efficiency between NT-PMMA and NT suspension

To compare the inactivation efficiencies of *S. aureus* and *E. coli* between the immobilization (NT-PMMA) and suspension (NT) systems, (NT-PMMA)₅ and 5 g L⁻¹ NT in suspension were tested under the same visible light condition. As shown in Figs. 7-2a and 7-2b, PMMA without a NT coating demonstrates a stable bacterial survival rate of approximately 91-105% for *S. aureus* and 97-119% for *E. coli* during 24 h. This indicates that in the absence of any disinfectant coating, there is steady bacterial growth on the plain PMMA surface. NT-PMMA exhibits significantly higher inactivation efficiency than the NT suspensions for both bacteria. For *S. aureus*, the NT-PMMA demonstrates a 96% inactivation efficiency (t = 360 min), whereas the inactivation efficiency of the NT suspension is 36%. As for *E. coli*, the NT-PMMA resulted in 62% inactivation efficiency (t = 360 min), which decreased to 43% in the NT suspension. After 24 h, the NT-PMMA achieved complete inactivation, whereas the NT suspension only achieved 81% and 72% inactivation efficacy for *S. aureus* and *E. coli*, respectively. Ananpattarachai et al. (2016) reported that a 1000 g L⁻¹ dose of NT suspension irradiated with visible light for 24 h resulted in only a 1-log-inactivation of *S. aureus* and *E. coli*, indicating the low photooxidation efficacy of the catalyst powder in suspension systems. It can be realized that such discrepancy is due mainly to the suffering of particle aggregation and light shading effect in a suspension system, consequently resulting in a decrease in inactivation efficiency. The production of ¹O₂ in both (NT-PMMA)₅ and NT suspension was verified

through ESR analysis using TEMP as a spin-trapped agent. TEMP was specifically chosen to capture $^1\text{O}_2$ and create the stable TEMP- $^1\text{O}_2$ adduct, identifiable by its characteristic ESR spectrum featuring three lines of equal intensity ($aN = 16 \text{ G}$). As illustrated in Fig. 7-2c, the distinct 1:1:1 triplet signal indicative of TEMP- $^1\text{O}_2$ adducts was observed, confirming the presence of $^1\text{O}_2$ in both the NT suspension and (NT-PMMA) $_5$. The presence of hydroxyl radicals in both systems was identified based on the observation of the typical 1:2:2:1 signal of DMPO-HO $^{\bullet}$ shown in Fig. 7-2d. However, the signal of $\text{O}_2^{\bullet-}$ was not found in the ESR spectra (Fig. B6-6). A similar result is shown in Fig. 7-2e, the H_2O_2 generated from (NT-PMMA) $_5$ showed a 1.5-fold higher concentration (0.92 mol L^{-1}) than that in NT suspension (0.63 mol L^{-1}). It is evidenced that the intensities of $^1\text{O}_2$, HO $^{\bullet}$, and H_2O_2 concentration of (NT-PMMA) $_5$ system are greater than in the NT suspension, corresponding to the greater inactivation efficiency of (NT-PMMA) $_5$ shown in Figs. 7-2a and 7-2b.

Figure 7-2. (a) The comparison of inactivation efficiency against *S. aureus* between plain PMMA, NT-PMMA, and NT suspension with the dose of 5 g L⁻¹ under visible-light intensity of 0.54 mW cm⁻². Conditions: [bacteria] = 10⁵ CFU mL⁻¹. (b) The comparison of inactivation efficiency against *E. coli* between plain PMMA, NT-PMMA, and NT suspension with the dose of 5 g L⁻¹ under visible-light intensity of 0.54 mW cm⁻². Conditions: [bacteria] = 10⁵ CFU mL⁻¹. (c) ESR spectra of (NT-PMMA)₅ and NT suspension. Conditions: [NT-PMMA] = 5 g L⁻¹, [NT suspension] = 5 g L⁻¹, T = 25 ± 1 °C. (d) ESR spectra of (NT-PMMA)₅ and NT suspension, and BQ as a quenching agent for O₂^{•-}. Conditions: [NT-PMMA] = 5 g L⁻¹, [NT suspension] = 5 g L⁻¹, T = 25 ± 1 °C. (e) H₂O₂ concentrations of (NT-PMMA)₅ and NT suspension. Conditions: [NT-PMMA] = 5 g L⁻¹, [NT suspension] = 5 g L⁻¹, T = 25 ± 1 °C.

7.4.4 Effects of NT dosage and visible light intensity on inactivation efficiency

The inactivation kinetics of the *S. aureus* and *E. coli* were compared by culturing the bacteria flushed from the NT-PMMA surface at various reaction times (Figs. 7-3a and 7-3b). In Fig. 7-3a, 5-log-inactivation of *S. aureus* treated with 1, 5, and 10 g L⁻¹ NT-PMMA under 0.54 mW cm⁻² visible light irradiation was achieved at 720, 540, and 60 min, respectively. On the other hand, 5-log-inactivation of *E. coli* treated with the same concentrations of NT-PMMA was achieved with longer reaction times, which are 900, 900, and 360 min. The disparity in inactivation efficiencies between the two bacterial types is attributed to the differences in their cell wall structures. Gram-positive bacteria have a thick cell wall (20-80 nm) made up of multilayered peptidoglycan (90%) that forms a three-dimensional lattice, while gram-negative bacteria have a thinner (10–15 nm) but more complex cell wall composed primarily of lipopolysaccharide (LPS) and a

few layers of peptidoglycan (around 2 nm thick) (Liu et al., 2023; Yen et al., 2022). As Figs. 7-2c and 7-2d showed that the photooxidation reaction of NT-PMMA was predominately driven by $^1\text{O}_2$. Valduga et al. (1993) indicated that gram-negative bacteria exhibited higher resistance to externally produced $^1\text{O}_2$ compared to gram-positive bacteria. Moreover, the outer membrane of gram-negative bacteria contains LPS, a compound comprising lipids and polysaccharides, which significantly limits the $^1\text{O}_2$ infiltration (Kim et al., 2019).

In Figs. 7-3c and 7-3d, it is evident that *S. aureus* achieved a 99.99% photo-inactivation efficiency after 720 min with the light intensity of 0.54 mW cm^{-2} , whereas *E. coli* achieved a 99.99% photo-inactivation efficiency after 1080 min with light intensity of 1.74 mW cm^{-2} . With the same light intensity of 0.54 mW cm^{-2} , *S. aureus* showed a 99.99% inactivation efficiency at 720 min, but it took *E. coli* 1260 min to achieve the same efficiency. The rapid photocatalytic reaction occurred on the surface of NT-PMMA, causing extensive damage to the bacteria. Overall, the inactivation efficiency against *S. aureus* and *E. coli* increases proportionally with increasing the coating of NT dosage and visible light intensity. A greater light intensity for *E. coli* inactivation is needed because *E. coli* is susceptible to the penetration damage of singlet oxygen. Table 8-1 summarizes similar studies and reveals that as-made NT-PMMA in this study showed excellent inactivation efficiency with a lower photocatalytic concentration under visible light irradiation than in other studies. For instance, Cantarella et al. (2016) embedded TiO_2 in PMMA with a 30-times higher dose of 150 g L^{-1} and achieved 4.8-log-inactivation of *E. coli* in 1 h using UV light. Tangudom et al. (2018) used a 3-times higher concentration of TiO_2 to achieve the same 5-log inactivation in 24 h, also with UV light irradiation.

Pascagaza-Rubio et al. (2022) immobilized TiO₂ on the HDPE surface with a dose of 46.7 g L⁻¹, showing only a 3-log inactivation of *E. coli* in 8 h under UVA light irradiation. However, there has been no notable advancement in the disinfection efficiency of TiO₂-immobilized matrices since the study conducted by Pascagaza-Rubio et al. (2022). The photooxidation efficiency of (NT-PMMA)₅ surpassed that of previous studies at a lower dose of only 5 g L⁻¹ and proved effective under visible light exposure.

Figure 7-3. The NT coating concentration on PMMA and its effect on the survival rates of (a) *S. aureus* and (b) *E. coli*. The visible light intensity affects on the survival ratio of (NT-PMMA)₅ against (c) *S. aureus* and (d) *E. coli*. Conditions: [NT] = 1 - 10 g L⁻¹, [bacteria] = 10⁵ CFU mL⁻¹, visible light intensity = 0.24 - 1.74 mW cm⁻², 25 ± 2 °C.

1 7.4.5 Reusability (stability) of NT-PMMA

2 On the other hand, durability is an important factor for photocatalysts in practical
3 applications. The resilience of NT-PMMA against both bacterial strains was assessed
4 over five consecutive cycles using a visible light intensity of 1.74 mW cm^{-2} (as shown in
5 Fig. 7-4a) and a 24-hour duration for each cycle. Throughout the five cycles, the
6 inactivation efficiency for *S. aureus* remained high at 99.99%, but it declined to
7 approximately 76% for *E. coli*. The findings are in line with data from Figs. 7-2a and 7-
8 2b further confirm that *S. aureus* is more susceptible to inactivation than *E. coli* due to
9 varying resistance levels against the $^1\text{O}_2$ -driven inactivation reaction. Another possible
10 cause is that the extracellular polymeric substances (EPS) produced by *E. coli* under
11 environmental stress will reduce the photooxidation capacity (Wang et al., 2023). In
12 order to overcome this issue, the coating concentration of NT-PMMA was increased to
13 20 g L^{-1} ((NT-PMMA)₂₀). Subsequent results, depicted in Fig. 8-4b, show that
14 inactivation efficiency against *E. coli* was 99.99% in the first cycle and maintained a
15 level of 99.4% throughout the subsequent four cycles. Notably, the performance of NT-
16 PMMA surpasses previous research. For comparison, a study by (Ye et al., 2013)
17 highlighted a 22% reduction in photooxidation efficiency for Rhodamine B using a TiO_2
18 thin film with 250 g L^{-1} after only four cycles under xenon lamp irradiation.

 3 of *S. aureus* and *E. coli*. Conditions: [NT] = 5 g L⁻¹, [bacteria] = 10⁵ CFU mL⁻¹, visible
 4 light intensity = 1.74 mW cm⁻², 25 ± 2 °C. (b) Reusability (stability) experiment of (NT-
 5 PMMA)₅ and (NT-PMMA)₂₀ for the photooxidation of *E. coli*. Conditions: [NT] = 5 and
 6 20 g L⁻¹, [bacteria] = 10⁵ CFU mL⁻¹, visible light intensity = 1.74 mW cm⁻², 25 ± 2 °C.

7 7.4.6 Modified Hom (MH) kinetic inactivation model

8 The photo-inactivation process usually comprises three phases, i.e., the lag
 9 (shoulder), log-linear, and tail phases, which are based on the concentration of bacteria
 10 under different damaged levels. To describe the variation of these inactivation phases,
 11 MH model has been developed, which has successfully simulated the photocatalytic
 12 inactivation of *E. coli* by CuFe₂O₄-Ti-GO (Ozkal, 2022), *S. aureus* and *E. coli* by double-
 13 layer ZnO/Al₂O₃, and *Klebsiella pneumoniae* by N/C-doped and N-
 14 tourmaline/palladium-C-codoped TiO₂ (Huang et al., 2020). In this study, two critical
 15 parameters, NT coating dosage and light intensity, were evaluated in determining the
 16 inactivation kinetics of NT-PMMA via the MH model. Fig. 7-5 shows the fitting curves

1 of the MH model for the inactivation of *S. aureus* and *E. coli* affected by these two
2 parameters. Table 7-2 summarizes that the experimental results fit well with the MH
3 model with low RMSE values. The MH model is useful in assessing the impact of
4 photocatalyst dosage and light intensity on the photo-inactivation performance of
5 bacteria. The constants k_1 (shoulder region), k_2 (log-linear region), and k_3 (tailing region),
6 which describe the inactivation of *S. aureus* and *E. coli*, decrease with increasing NT
7 coating concentrations and light intensity. The constant k_1 (shoulder region) can illustrate
8 the sequential process, where cellular damage accumulates over time instead of inducing
9 immediate lethality (Huang et al., 2019). In this study, the value of constant k_1 (shoulder
10 region) positively correlates with initial inactivation efficiency (the first 480 min). At the
11 NT doses of 5 and 10 g L⁻¹, *E. coli* showed higher k_1 values than *S. aureus* because of the
12 higher resistance to the ROSs attack. Similarly, *E. coli* showed a higher k_1 value than *S.*
13 *aureus* with the same visible light intensity of 0.54 mW cm⁻², corresponding to the results
14 in Figs. 7-2a and 7-2b that *E. coli* has greater resistance than *S. aureus* to the ¹O₂
15 dominant system.

1 **7.4.7 Biophysical properties of the damaged bacteria**

2 The biophysical properties of the inactivated bacteria on NT-PMMA
3 composite were examined using atomic force microscopy (AFM). The AFM was used to
4 observe cells in real time under hydrated conditions without staining or dehydration. At 0
5 min, *S. aureus* appeared spherical (Fig. 7-6a), and *E. coli* appeared rod-shaped (Fig. 7-
6 6c). After 24 h of contact with NT-PMMA, *S. aureus*'s cell structure decomposed due to
7 ROSs attacks, whereas *E. coli* remained largely intact, consistent with the inactivation
8 performance results shown in Figs. 7-2a and 7-2b. After 24 h, *S. aureus*'s bacterial cell
9 height on NT-PMMA decreased by 42%, from 292.6 ± 27.8 nm to 170.5 ± 39.7 nm, and
10 the surface roughness increased by 91%, from 6.65 ± 2.18 nm to 12.7 ± 3.9 nm.
11 Conversely, the height of *E. coli* experienced a significant reduction of 53%, decreasing
12 from an initial measurement of 187.6 ± 9.9 nm to 89.2 ± 14.3 nm. In parallel, there was a
13 notable 97% increase in surface roughness, rising from 6.35 ± 2.2 nm to 12.5 ± 4.8 nm.
14 These alterations in bacterial height and surface roughness can be ascribed to the
15 oxidative attack from $^1\text{O}_2$, HO^\bullet , and H_2O_2 generated by (NT-PMMA)₅ on the bacterial
16 membranes. This attack leads to the depletion of intracellular components, including the
17 loss of potassium ions (K^+) (Yen et al., 2022) and protein (Liu et al., 2023). As
18 mentioned in section 7.4.4, the major component, LPS, in the cell wall of Gram-negative
19 bacteria plays a major role in reducing the penetration of singlet oxygen. Therefore, the
20 photooxidation reaction of NT-PMMA was predominately driven by $^1\text{O}_2$, resulting in
21 more severe damage on gram-positive bacteria than on gram-negative bacteria. The
22 defensive ability of LPS against $^1\text{O}_2$ can be observed in the cellular morphology in Figs.

- 1 7-6b and 7-6d, showing the relatively significant alternation of *S. aureus* and miner
 2 impact on *E. coli* after 24 h.

- 3
 4 Figure 7-6. AFM images of *S. aureus* after reacting with NT-PMMA for (a) 0 h, (b) 24 h;
 5 *E. coli* after reacting with NT-PMMA for (c) 0 h, (d) 24 h. The (e) bacterial height and (f)
 6 surface roughness of *S. aureus* and *E. coli* after reacting with NT-PMMA for 0 h and 24
 7 h. Conditions: [NT] = 5 g L⁻¹, [bacteria] = 10⁸ CFU mL⁻¹, visible light intensity = 0.54
 8 mW cm⁻², 25 ± 2 °C.

9 7.4.8 Photo-inactivation mechanism of NT-PMMA

- 10 Fig. 7-7 illustrates the photocatalytic inactivation mechanism of NT-PMMA
 11 against *S. aureus* and *E. coli*. The generation of ROSs under visible light irradiation via
 12 the route of reaction equations is shown in Eqs. 6-11. These reactions involve photons
 13 with a compatible wavelength bombarding the photocatalyst's surface, exciting electrons
 14 (e^-) from the valence band to the conduction band (e_{CB}^-) and leaving a positive hole

1 (h_{VB}^+). The electron-hole pair then reacts with a water molecule in the environment, with
 2 the positive hole (h_{VB}^+) splitting the water and generating HO• and hydrogen ions (H⁺)
 3 (Chen et al., 2020; Lin et al., 2015) (Eqs. (7)-(8)). The electron in the conduction band
 4 (e_{CB}^-) reacts with oxygen and H₂O₂, resulting in the formation of a positive hole (h_{aq}^+),
 5 ¹O₂, and HO• radicals (Eqs. (10)-(11)). As such, ¹O₂, HO•, and H₂O₂ play a dominant role
 6 in the photo-inactivation mechanism, the same as the findings in Tzeng et al. (2022).
 7 Differently, Tzeng et al. (2022) only examined ROSs in the NT suspension system
 8 instead of comparing the suspension and immobilization systems. In this work,
 9 immobilization of NT on PMMA can substantially minimize the reactant turbidity and
 10 exclude particle aggregation, subsequently the light is fully utilized and improving
 11 photocatalytic efficiency. The ROSs generated on the (NT-PMMA)₅ surface were proved
 12 to have a stronger intensity than NT suspension (Figs. 7-2c and 7-2d), which can
 13 decompose the target bacteria more efficiently because of the lack of turbidity
 14 interference, uniform distribution of NT, and the shorter diffusion distance for ROSs
 15 directly reacting with the bacteria.

1

2 Figure 7-7. Proposed photo-inactivation mechanism of NT-PMMA against *S. aureus*3 (*Gram-positive bacteria*) and *E. coli* (*Gram-negative bacteria*).4 **7.5 Conclusions**

5 This study demonstrated that NT-PMMA could effectively eliminate both *S.*
6 *aureus* and *E. coli* bacteria under visible light irradiation. The transmittance of the (NT-
7 PMMA)₅ remained high at 92%, even when equipped with a self-inactivation film,
8 suggesting that it is a promising alternative to glass. The inactivation efficiency of (NT-
9 PMMA)₅ against *S. aureus* and *E. coli* reached 99.9% within 24 h under various visible
10 light intensities. NT-PMMA showed higher intensities of 1O_2 , HO^\cdot , and higher
11 concentration of H_2O_2 than NT suspension, implying the greater inactivation efficiency of
12 immobilized NT on PMMA than in NT-suspension. The immobilization approach
13 enhanced the inactivation performances of NT-PMMA, making it superior to NT
14 suspension due to the absence of turbidity interference and the uniform distribution of

1 NT. Remarkably, NT-PMMA sustained a 99.99% inactivation rate against *S. aureus* over
2 five cycles of photooxidation due to cell disruption induced by $^1\text{O}_2$, HO^\bullet , and H_2O_2
3 attacks. Thus, the above results indicate that the inactivation efficiency of NT-PMMA has
4 been substantially improved by immobilization and has a potential for bacterial
5 inactivation. Future research will further explore the structural characterization of NT-
6 PMMA after repeated use, investigate the presence of bacterial biofilm residues on its
7 surface, and assess their impact on disinfection efficiency.

CHAPTER 8

CONCLUSIONS

1 MetaVT has been historically applied to plants in calcareous soil to mitigate Fe
2 chlorosis, although past studies have reported its extremely low solubility in electrolyte
3 solutions. This study expands on previous research by evaluating the effectiveness of
4 nano-metaVT and nano-CT-metaVT under various conditions, as detailed across three
5 chapters. In Chapter 2, results show that nano-CT-metaVT-KCl has a lower total soluble
6 iron (Fe) concentration than nano-metaVT-KCl, attributed to the slow-release properties
7 of the CT coating. Conversely, in SPE suspensions, nano-CT-metaVT exhibits higher
8 total soluble Fe than nano-metaVT, contradicting findings from previous research.
9 Additionally, inoculation with *Pp* Pf-5 enhances total soluble Fe concentrations and
10 lowers pH in both nano-metaVT-SPE and nano-CT-metaVT-SPE compared to treatments
11 without microbes, highlighting the influential role of soil microbes. However, the total
12 soluble Fe concentrations in both nano formulations in SPE are still lower than those
13 observed in KCl suspensions, highlighting factors such as CT coating, microbial
14 inoculation, and the presence of organic/inorganic ligands that affect solubility.

15 In Chapter 3, the study explores the performance of these nano-formulations with
16 winter wheat grown in silica sand amended with a modified $\frac{1}{2}$ HS (pH 8.4). Although
17 results are inconclusive within a 14-day growth period, *Pp* Pf-5 inoculation appears to
18 mitigate salinity stress by increasing plant transpiration rates, without interference from
19 nano-metaVT or nano-CT-metaVT on root colonization. Chapter 4 extends this
20 investigation to wheat and beans grown in calcareous and salt-affected soils. Here, nano-
21 CT-metaVT treatments significantly enhance bean root dry mass, and nano-metaVT
22
23

1 treatments improve chlorophyll content within a 28-day growth period. After 50 days,
2 both treatments led to an increase in the number of flowers and buds in beans compared
3 to controls, demonstrating their potential to enhance growth and productivity.
4 Furthermore, these nano-fertilizers exhibit lower environmental impacts by minimizing
5 Fe leaching, confirming their stability and reduced environmental footprint. Overall, the
6 effectiveness of nano-metaVT and nano-CT-metaVT is influenced by various factors,
7 including plant type, growth conditions, the presence of abiotic stresses, and the time
8 necessary for mineral weathering, which provide insight to research further investigating
9 the mechanism in agricultural settings in the future.

10 Chapters 7 and 8 examine the disinfection efficiency of HOS and NT-PMMA.
11 The research findings from Chapter 6 indicate that cell permeability plays a pivotal role
12 in the HOS disinfection process. The structural differences in cell walls lead to varying
13 levels of permeability damage between *S. aureus* and *E. coli*. Additionally, the analysis
14 revealed that singlet oxygen is a critical component in the disinfection mechanism
15 induced by HOS treatment. In Chapter 7, immobilization proved to enhance the
16 antibacterial activity of NT-PMMA, making it more effective than NT suspension. This
17 high level of bacterial inactivation was achieved through cellular disruption caused by
18 attacks from ROSs such as $^1\text{O}_2$, HO^\bullet , and H_2O_2 . Consequently, these results indicate that
19 the inactivation efficiency of NT-PMMA has been significantly improved through
20 immobilization, indicating the potential for effective bacterial inactivation in various
21 applications.

22

1 Lastly, Chapters 7 and 8 assess the disinfection efficiency of heated oyster shells
2 (HOS) and nitrogen-doped titanium dioxide-coated polymethyl methacrylate (NT-
3 PMMA). The findings in Chapter 6 provide evidence that cell permeability is crucial in
4 the HOS disinfection process and that cell wall structure results in different levels of cell
5 permeability damage between *S. aureus* and *E. coli*. Furthermore, analysis of the ROS
6 induced by HOS treatment revealed that singlet oxygen plays an essential role in the
7 disinfection mechanism. In Chapter 7, the immobilization approach enhanced the
8 inactivation performances of NT-PMMA, making it superior to NT suspension due to the
9 absence of turbidity interference and the uniform distribution of NT. Remarkably, NT-
10 PMMA sustained a 99.99% inactivation rate against *S. aureus* over five cycles of
11 photooxidation due to cell disruption induced by $^1\text{O}_2$, HO^\bullet , and H_2O_2 attacks. Thus, the
12 above results indicate that the inactivation efficiency of NT-PMMA has been
13 substantially improved by immobilization and has a potential for bacterial inactivation.

Substantial improvement in photocatalysis performance of N-TiO₂ immobilized on PMMA: Exemplified by inactivation of Staphylococcus aureus and Escherichia coli

B.3 Supplemental information for Chapter 3

Table B3-1. Composition of the modified half-strength Hoagland solution.

Component		Final Concentration
Potassium nitrate	KNO_3	0.2525 g/L
Calcium nitrate	$\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$	0.59 g/L
Magnesium sulfate	$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	0.2465 g/L
Ammonium nitrate	NH_4NO_3	0.04 g/L
Monopotassium phosphate	KH_2PO_4	0.034 g/L
Boric acid	H_3BO_3	0.00143 g/L
Manganese chloride	$\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$	0.000905 g/L
Zinc sulfate	$\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$	0.00011 g/L
Copper sulfate	$\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$	0.0000255 g/L
Sodium molybdate	$\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$	0.00006 g/L

Figure B3-1. The shoot water content (%) wheat grown in the sand with the four Fe treatments (control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA) without salinity stress and under salinity stress. A three-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figure B3-2. The root length of wheat grown in the sand with the four Fe treatments (control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA) without salinity stress and under salinity stress. A three-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figure B3-3. The root dry mass of wheat grown in the sand with the four Fe treatments (control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA) without salinity stress and under salinity stress. A three-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figure B3-4. The pH (a) and EC (b) of sand pore water (SPW) after wheat grown in the sand with the four Fe treatments (control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA) without salinity stress and under salinity stress. A three-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figure B3-5. The shoot P (a) and root P (b) concentrations of wheat grown in the sand with the four Fe treatments (control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA) without salinity stress and under salinity stress. A three-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figure B3-6. The shoot K (a) and root K (b) concentrations of wheat grown in the sand with the four Fe treatments (control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA) without salinity stress and under salinity stress. A three-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figure B3-7. Pictures of *Pp* Pf-5 from sand pore water extraction cultured on TSA medium without salinity stress (b) (EC = 1.3 dS·m⁻¹) and under salinity stress (c) (EC = 10 dS·m⁻¹).

B.4 Supplemental information for Chapter 4

Figure B4-1. Root-associate P (a, b), Na (c, d), and K (e, f) of wheat (a, c, e) and beans (b, d, f) grown in the sand with four Fe treatments, control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA, and irrigated with ddH₂O and saline water (EC = 4 dS·m⁻¹). A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figure B4-2. Rhizosphere soil pH (a, b) and EC (c, d) of wheat and beans grown with four Fe treatments, control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA, and irrigated with ddH₂O and saline water (EC = 4 dS·m⁻¹). Experimental condition: pH and EC were measured soil extract prepared with a soil-to-water ratio of 1:1. A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figure B4-3. Bulk soil pH (a, b) and EC (c, d) of wheat and beans grown with four Fe treatments, control, nano-metaVT, nano-CT-metaVT, and Fe-EDDHA, and irrigated with ddH₂O and saline water (EC = 4 dS·m⁻¹). Experimental condition: pH and EC were measured with saturated soil paste extract. A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard error calculated with the statistical mix model.

Figure B4-4. EDS semi-quantitative results of nano-metaVT and nano-CT-metaVT

weathering in soil with wheat growing from one to four weeks. Three nano-metaVT/nano-CT-metaVT particles were analyzed each time. A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard deviation of the three replicates.

Table B4-1. The mobility of DTPA-extractable Fe in the soil columns without wheat. A two-way ANOVA was performed. Different letters above columns represent significant differences between treatments based on the Tukey-Kramer test ($\alpha \leq 0.05$). Error bars represent the standard deviation of the three replicates.

unit: mg kg ⁻¹	control	metaVT	CT- metaVT	Fe-EDDHA
Initial DTPA-Fe concentrations in the top layers (0.4 cm; 160 mg Fe kg ⁻¹)	6.0 ± 0.2	10.0 ± 0.7	10.6 ± 0.3	114.7 ± 10.9
Layer 1	6.1 ± 0.4 ^c	7.8 ± 0.7 ^{ab}	7.9 ± 0.4 ^a	7.1 ± 0.6 ^{abc}
Layer 2	5.9 ± 0.2 ^c	6.7 ± 0.5 ^{abc}	7.2 ± 0.5 ^{abc}	6.8 ± 0.5 ^{abc}
Layer 3	5.9 ± 0.3 ^c	6.6 ± 0.4 ^{abc}	7.1 ± 0.5 ^{abc}	7.2 ± 0.6 ^{abc}
Layer 4	6.2 ± 0.5 ^{bc}	6.5 ± 0.5 ^{abc}	6.8 ± 0.6 ^{abc}	7.1 ± 0.7 ^{abc}
Layer 5	6.3 ± 0.4 ^{bc}	6.5 ± 0.8 ^{abc}	7.4 ± 0.3 ^{abc}	7.0 ± 0.6 ^{abc}

B.5 Supplemental information for Chapter 6

Table B5-1. Metal element analysis of HOS using inductively coupled plasma-optical emission spectrometry (ICP-OES).

Element	ppm
Cu	0.1
Ag	0.1
Ca	18,094
Fe	5.0
Zn	0.3

Figure B5-1. CaO disinfection efficiency against *S. aureus* and *E. coli*. Experimental conditions: [CaO] 0.20 g/L, pH= 12.0 ± 0.1 , [bacteria] 10^5 CFU/mL, T = 25 ± 1 °C.

Figure B5-2. (a) ESR spectra of HOS obtained with DMPO as a spin-trapping agent and tert-Butanol (TBA) as a quenching agent. (b) ESR spectra of HOS obtained with DMPO as a spin-trapping agent and p-Benzoquinone (BQ) as a quenching agent. Experimental conditions: [HOS] = 1 g/L, [TBA] = 0.01 M, [BQ] = 0.01 M, $T = 25 \pm 1$ °C.

Figure B5-3. ABDA absorbance reduction at 380 nm of MB at 0 and 30 min under white light irradiation (30 mW). Experimental conditions: [MB] = 50 $\mu\text{g}/\text{mL}$, [ABDA] = 0.005 M, wavelength = 380 nm, $T = 25 \pm 1$ $^{\circ}\text{C}$.

3

4

5 Figure B6-5. PL spectra of N-TiO₂.

6

1

2

3 Figure B6-6. ESR spectra of (NT-PMMA)₅ and NT suspension, and TBA as a quenching4 agent for HO•. Conditions: [NT-PMMA] = 5 g L⁻¹, [NT suspension] = 5 g L⁻¹, T = 25 ± 1

5 °C.

Table B6-1. Characterization of N-TiO₂.

	XRD	SEM	UV-vis		BET			
	Phase content ^a	Crystalline size ^b	Particle size	Band gap ^c	Specific surface area	Pore size	Pore volume	Adsorption type ^d
	A/R/B (%)	nm	nm	eV	m ² /g	nm	cm ³ /g	cm ³ /g
NT	100/00/0	37	20	2.4	45.3	6.9	0.13	IV

^a A, R, and B denote anatase, rutile, and brookite, respectively.

^b The crystalline size was determined using the Scherer formula.

^c The band gap is determined by the plot of $(\alpha h\nu)^{1/2}$ versus photon energy.

^d Adsorption isotherm type & hysteresis loop were based on the IUPAC manual.

Appendix D. Standard Operating Procedures (SOPs)

D.1 Synthesis of nano-metaVT and nano-CT-metaVT

1. Nano-metaVT will be synthesized according to the protocols described by Ammari & Hattar (2011). The synthesis is conducted in an ice bath in an argon gas chamber to eliminate oxygen and allow ferrous ions to be present.
2. Five grams monoammonium phosphate $[(\text{NH}_4)\text{H}_2\text{PO}_4]$ is dissolved in 200 mL deionized water to form a solution with a PO_4^{3-} concentration of 0.217 M. After stirring for 30 min,
3. Fifteen grams ferrous sulfate ($\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$) is slowly added to the solution, to create a solution with a Fe concentration of 0.270 M.
4. The solution is kept stirring for 30 min. Then the pH of the suspension will be adjusted to pH 6.5 by dropwise additions of 1.25 mM NaOH. A pale-blue precipitate will appear.
5. The resulting vivianite precipitate will be washed several times with deionized water until the EC of the mixture is below $0.2 \text{ dS} \cdot \text{m}^{-1}$.
6. The precipitate will be centrifuged at $6,000 \times g$ for 15 min, the residual water will be removed, and the pellet will be dried in a freeze-dryer (FreeZone Benchtop Freeze Dryer, Labconco).
7. A chitosan (CT) solution will be prepared by dissolving 1 g CT in 200 mL 0.1 M acetic acid (CH_3COOH) solution while stirring.
8. After 12 h, 4 g of metavivianite powder is slowly added to the CT solution and stirred for an additional 30 min.
9. The pH of the suspension will be adjusted to 6.5 by adding 1.25 mM NaOH.
10. The nano-CT-metaVT precipitate is rinsed with deionized water until salt-free ($< 0.2 \text{ dS} \cdot \text{m}^{-1}$).
11. The precipitate is centrifuged at $6,000 \times g$ for 15 min, the residual water is removed, and the pellet is freeze-dried.

Note: The whole synthesis process is conducted in a Argon chamber to minimize the oxidation, and in an ice bath to keep at the temperature around 4°C .

D.2 Atomic Absorption Spectroscopy (Varian AA240)

1. Turn on the heater that is connected to Nitrous Oxide (N_2O).
2. The heater can prevent the ice from blocking the tube, which would pose an explosion hazard.
3. Take off the hinged door in front of the burner assembly. (Burner assembly drainage box)
4. Change the burner head to the one specific for N_2O .
5. Check whether the slot of the burner head is clean or not. If not, clean by using DI water and put the door back.
6. Turn on the power of AA, and followed by the computer and the SpectrAA software.
7. In the software:
 - Add a new worksheet → add Fe (or other elements of interest)
 - [Type/Mode] edit the sampling method Manual; flame type N_2O /Acetylene; N_2O flow 10.5
 - [Measurement] edit read delay 5 sec
 - [Optical] edit lamp position 1; lamp current 13 mA; background correction BC on
 - [Standard] type in the concentration of standard solutions (not include 0 ppm); conc decimal places 4
 - [Analysis]
8. Open the acetylene cylinder (Check the pressure of acetylene cylinder > 400 kPa, or the acetone in the bottom of the cylinder will go out from the tube and cause the hazard)
 - Open N_2O (with heater is turned on)
9. Open the air valve
 - click optimize → optimize the lamp
 - Adjust the location of the stage (use a card)
 - Adjust the nob on the lamp to make the signal greater
 - Turn on the Flame
10. If finished, turn off the flame → AA → software → computer

D.3 Making Luria-Bertani (LB) Medium

1. Place a large weigh boat on a balance and measure out 5 g of Tryptone 1. Add all of it to a volumetric flask 2.
2. If any dust remains stuck to the weigh boat afterwards, use a spray bottle filled with double distilled water to remove it.
3. Place a large weigh boat on a balance and measure out 2.5 g of Yeast Extract. Add all of it to the volumetric flask.
4. If any dust remains stuck to the weigh boat afterwards, use a spray bottle filled with double distilled water to remove it.
5. Add ddH₂O to the volumetric flask until it reaches 500 mL.
6. Place the solution on a stir plate 3 until it is a bright gold color, which indicates that the solution is fully dissolved.
7. After several minutes of mixing, remove the volumetric flask from the stir plate and place in a 1 Liter Erlenmeyer flask.
8. If making solid media, add 10 g of agar and stir using a stir plate. This addition must be done after transferring to the Erlenmeyer flask.
9. Cover the opening of all flasks with two layers of aluminum foil. Label each flask with labeling tape specifying the date and that it is LB medium.
10. Autoclave for 30 minutes 4, plus time to cool. Remove from autoclave after the cycle ends.
11. If making solid media, allow to cool slightly then pour into petri dishes. If making liquid media, allow to completely cool to room temperature before use.

Notes:

1. Solids were added before any of the water for convenience based on our lab setup.
2. The solution was mixed in a volumetric flask instead of an Erlenmeyer flask for convenience of working in our lab. It was then transferred to an Erlenmeyer flask to be autoclaved. Also, volumetric flasks are more accurate than graduated cylinders.
3. We used our stir plate to stir all solutions to ensure a good mix and for convenience.
4. This corresponds to the program we run on our autoclave for media solutions. We use this duration to assure that solutions are not overcooked.
5. This method is based on a method provided by Matthew Potter.

D.4 Making Minimal Medium

1. Measure out the following chemicals in the specified amounts ¹ and add to a volumetric flask ². This is the **Salt Solution**.

	<u>1 L</u>	<u>500 mL</u>	<u>200 mL</u>
K ₂ HPO ₄	10.5 g	5.25 g	2.1 g
KH ₂ PO ₄	4.5 g	2.25 g	0.9 g
Na*Citrate*2H ₂ O	0.5 g	0.25 g	0.1 g
(NH ₄) ₂ SO ₄	1 g	0.5 g	0.2

2. Add ddH₂O to the volumetric flask until it reaches the desired volume⁷. Pour back into flask and stir using a stir plate ³.
3. Add 2 g of sucrose and 0.125 g MgSO₄*ANHYDROUS (or 0.25 g MgSO₄*7H₂O) to a small Erlenmeyer flask. Add 10 mL of ddH₂O using an electrical pipette ⁴ and stir using a stir plate. This is the **C & Mg Solution**.
4. Transfer the salt solution to a Erlenmeyer flask².
5. Add 2 g of agar to the **Salt Solution** for every 100 mL of medium (see table below). Swirl to disperse and stir using stir plate ³.

	<u>1 L</u>	<u>500 mL</u>	<u>200 mL</u>
Agar	20 g	10 g	4 g

6. Cover each flask with two layers of aluminum foil, label each flask, and auto clave⁵ the **Salt Solution** and the **C & Mg Solution** for 30 minutes, plus time for cooling ⁶.
7. Allow to cool slightly, then add 1 mL of the **C & Mg Solution** to the **Salt Solution** for every 100 mL of **Salt Solution** (see table below).

	<u>1 L</u>	<u>500 mL</u>	<u>200 mL</u>
C & Mg Solution	10 mL	5 mL	2 mL

8. Wait until the flask is cool to the touch then pour the solution into petri dishes.

Notes:

1. Salts were added before any of the water for convenience based on our lab setup.
2. If making 1 liter, use a 2 liter Erlenmeyer flask. If making 500 mL or 200 mL, a 1 liter flask will work. The solution was mixed in a volumetric flask instead of an Erlenmeyer flask for convenience of working in our lab. It was then transferred to an Erlenmeyer flask to be autoclaved. Also, volumetric flasks are more accurate than graduated cylinders.
3. We used a stir plate to stir all solutions to ensure a good mix and for convenience.
4. Small measurements of liquids are made using an electrical pipette for accuracy.
5. Do not autoclave volumetric glassware! Make sure that the solution was transferred to Erlenmeyer flask in step 4.
6. This corresponds to the program we run on our autoclave for media solutions. We use this duration to assure that solutions are not overcooked.
7. 500 mL makes about 25 Petri dishes worth of media.
8. This method is based on a method provided by Matthew Potter.

D.5 Method of for preparing *PcO6/Pp Pf-5* bacterial suspension

1. Place bullet tube of *PcO6* on minimal media agar plate; spread. Seal plate.
2. 36-48 hours later, flood the plate with 10 mL sterile ddH₂O¹.
3. Rotate plate and agitate gently to suspend mobile cells. If necessary, gently scrape the surface of the media with a sterile spatula. Do not penetrate the media surface.
4. Transfer 1 mL of cell suspension to a sterile centrifuge tube.
5. Using sterile centrifuge tubes, serially dilute cells by 1:10 in sterile ddH₂O 4 times, switching pipette tips each time a new solution is drawn from.
6. Add 1 mL from the final serial dilution to 99 mL sterile ddH₂O in a beaker.
7. The objective is to achieve a concentration of 1×10^4 . Confirm that this is the approximate concentration of the final solution using a spectrophotometer to measure optical density at the 600 nm wavelength. An OD 600 measurement of 0.1 A correlates to about 10^8 CFU/mL. According to this method, if the 1:100 solution (second serial dilution) reads approximately 0.1 A on OD 600, this method should achieve the correct concentration. If this is not the case, adjust the dilutions as needed to achieve the correct concentration.

Note: This method is based on a method provided by Josh Hortin.

D.6 Making Hoagland's Solution (Modified)

This recipe is for a full-strength solution. To prepare a half-strength solution, double the water that the stock solutions are added to (use 2 L of water instead of 1 L).

Component		Stock Solution (g/L)	Stock Solution (g/ 250 mL)	Stock/L solution	Final Concentration (g/L)
Potassium nitrate	KNO ₃	101	25.25	5 mL	0.505
Calcium nitrate	Ca(NO ₃) ₂ *4H ₂ O	236	59	5 mL	1.18
Magnesium sulfate	MgSO ₄ *7H ₂ O	246.5	61.63	2 mL	0.493
Ammonium nitrate	NH ₄ NO ₃	80	20	1 mL	0.08
Monopotassium phosphate	KH ₂ PO ₄	68	17	1 mL	0.068
Boric acid	H ₃ BO ₃	2.86	0.715	1 mL	0.00286
Manganese chloride	MnCl ₂ *4H ₂ O	1.81	0.453	1 mL	0.00181
Zinc sulfate	ZnSO ₄ *7H ₂ O	0.22	0.055	1 mL	0.00022
Copper sulfate	CuSO ₄ *5H ₂ O	0.051	0.0128	1 mL	0.000051
Sodium molybdate	Na ₂ MoO ₄ *2H ₂ O	0.12	0.03	1 mL	0.00012

Mix each stock solution in a separate 250 mL sealable container. This is done by adding the appropriate amount of each chemical to the container, and then adding ddH₂O until a volume of 250 mL is reached. These stock solutions can be stored for 6 months in the refrigerator. Within three days of using the Hoagland's solution, add the appropriate amount of stock solution to ddH₂O according to the table above. Agitate the final solution before adding to pots.

Notes:

1. This concentration was listed in terms of half liters in Matthew Potter's original method³. It was converted to terms of Liters by Justin Deakin. Li-Ting Yen modified the concentrations of the stock solution, preventing the stock solution from precipitating out (11/26/2022).
2. The stock solutions cannot be stored premixed. Each salt solution must be mixed and stored separately or the salts will precipitate out.
3. The separate stock solutions can be stored in the refrigerator for up to 6 months.
4. All water added to the Hoagland solution should be double-deionized water (resistance >18 M Ω cm) to ensure that the chemical concentrations stated here are the actual concentrations of the final solution.
5. Working solution should be prepared immediately before use. Do not store working solution for more than 3 days.

³ Potter, M., Deakin, J., Cartwright, A., Hortin, J., Sparks, D., Anderson, A. J., McLean, J. E., Jacobson, A., & Britt, D. W. (2021). Absence of nanoparticle-induced drought tolerance in nutrient sufficient wheat seedlings. *Environmental Science & Technology*, 55(20), 13541-13550.

D.7 Wheat harvest instructions

Time Estimate: 6 - 9 hours

1. Record the weight of the magenta box.
2. Pour 45 mL DI water into the magenta box, and let it sit for 15 minutes.
 - a. Take photos
3. Separate the shoots from the roots by cutting at upper part of the coleoptile
4. Measure and record the maximum length of shoots via a ruler
 - a. Take photos
5. Pour the pot of sand with root on a new and clean zip bag
6. Pick and dip plant roots in a 250-mL beaker of water to remove extra sand via a tweezer, then place the plant on a paper towel.
 - a. Replace root rinsing water between triplicates
 - b. Acid rinse beaker between treatments
7. Measure and record the maximum length of roots and shoots via a ruler
 - a. Stretch roots for maximum length
 - b. Take photos
8. Add roots and shoots to a respective paper envelope
9. Measure and record the wet weight of root and envelope and shoots and envelope
10. Vacuum separates the sand/water mixture into a sterile centrifuge tube to extract the liquid fraction of the sample. Measure pH and EC of sand pore water.
11. The sand pore water will be centrifuged at $20,800 \times g$ for 30 minutes, filtered through a syringe filter ($0.22 \mu\text{m}$), and acidified after measuring pH and EC. The sand pore water will be stored in the refrigerator for later analysis.
12. The shoot and root tissue will be dried at $60 \text{ }^\circ\text{C}$ for 48 hours. Before measuring the dry weight, make sure they are cooled down.
13. After measuring the dry weight, two sterilized tweezers will be used to remove the sand grains held by the root.

D.8 Measurement of humic and fulvic acid

Chemical preparations

1. 0.1 M HCl (Mw=36.46 g/mol, 37%, Density: 1.2 g/L; 8.2 mL for making a 1 L solution) Make 2 L
2. 6 M HCl (4.927 mL for making a 10 mL solution) Make 10 mL
3. 0.1 M NaOH (Mw=40 g/mol; 4g / 1L) Make 2 L
4. 0.1 M KOH (Mw=56.11 g/mol; 5.611 g / 1L) Make 1 L

Resin cleaning

1. Every new resin batch was first cleaned to remove organic impurities with five 0.1 M HCl extractions (24 h). This cycle was repeated with 0.1 M NaOH.
2. The resin was thoroughly cleaned by Soxhlet extractions with acetonitrile and methanol, each for 24 h. The cleaned resin was stored in methanol.
3. The methanol was removed by placing the resin in a Buchner funnel with a Whatman 41 filter and washing under vacuum with water having a volume 20 times that of the resin.
4. The resin was similarly rinsed with 0.1 M HCl, having 10 times the resin volume. It was found that 250 g of resin could be cleaned sufficiently by rinsing with 2 L of demineralized water and 1 L of 0.1 M HCl.

Batch Procedure

1. About 50 mL of a sample solution (V1) was adjusted to pH 1 with 6 M HCl (V2) to precipitate the dissolved HA.
2. After standing overnight, the suspension was centrifuged (10 min, 3000g).
3. The supernatant was decanted (V3; the difference between V1 and V3 is the water volume retained in the HA pellet) and subsampled for DOC analysis (representing the sum of dissolved FA, Hy, and HON, $\text{DOC}_{\text{FAHyHON}}$)
4. A 10 g portion of cleaned DAX-8 resin was added to the remaining supernatant (V4,L; this is essentially V3 minus the volume taken for DOC analysis) to adsorb the FA (and HON) fraction.
5. After 1 h of equilibration by continuous tumbling, the suspension was filtered. The resin was equilibrated in four subsequent steps (1 h each) with 20 mL of 0.1 M KOH (V_{11,i}).
6. Meanwhile, the pellet of precipitated HA was dissolved in 0.1 M KOH (V5) and analyzed for DOC (DOC_{HA}).

Blank experiment

1. Ten grams of moist DAX-8 resin was added to 50 mL of 0.1 M HCl (V4_{BL}) after previous DOC analysis (DOC_{BL1}).

Appendix E. Safety and chemical hygiene

This revised safety and chemical hygiene plan are based on the standard lab safety regulations in Dr. Jacobson's laboratory.

E.1 Biological Hazards

All waste contaminated with *PcO6/Pp* Pf-5 will be autoclaved before disposal, including Petri dishes, centrifuge tubes, gloves, and aluminum foil placed on countertops contacted with *PcO6/Pp* Pf-5. The sand matrix inoculated with *PcO6/Pp* Pf-5 or used to grow seeds was also autoclaved before discarding. To minimize contamination, gloves will be worn at all times during the whole experiment dealing with *PcO6/Pp* Pf-5. In addition, all instruments and lab benches used to handle *PcO6/Pp* Pf-5 will be sanitized with ethanol before and after use.

E.2 Chemical Hazards

Each prepared solution will be labeled with the name of the solution, the date, and the researcher's name (space permitting) or initials. Gloves, eye protection, and a lab coat will be worn at all times in the laboratory. The following chemicals to be used in the experiments require only gloves, eye protection, and a lab coat to handle: bleach (6%), hydrogen peroxide (30%), potassium nitrate, calcium nitrate, magnesium sulfate, ammonium nitrate, monopotassium phosphate, boric acid, manganese chloride, tryptone, yeast extract, agar, potassium phosphate dibasic, potassium phosphate monobasic, sodium citrate dihydrate, ammonium sulfate, sucrose, magnesium sulfate, copper sulfate, zinc sulfate, and sodium molybdate. These ingredients are used to prepare minimal medium, LB medium, and the modified, half-strength Hoagland's solution and sterilize the seeds. After use, the minimal and LB media will be disposed of as bio-waste, as they will be

contaminated with microbes. Bleach (6%) will also be used to sanitize pots and laboratory surfaces. Hydrogen peroxide solutions will be diluted to 10% before disposal, with additional water to ensure flushing and dilution.

All sand/soil to which NPs are added will be collected in 5-gallon buckets to be disposed of by USU Environmental Health and Safety (EHS). Gloves, weigh boats, and all other disposable lab supplies used to handle concentrated NPs will be stored in gallon zip lock bags, which will also be disposed of by EHS. Whenever concentrated NPs are handled, required PPE will include gloves, a lab coat, eye protection, and an N-95 dust mask. All areas and scales where NPs or sand/soil containing NPs are handled will be carefully cleaned with a brush immediately after use. NPs will be stored, protected from light, in a marked container.

When handling liquid nitrogen, extreme caution will be exercised. PPE will include a lab coat, insulated gloves, and eye protection. A face shield will be worn when pouring liquid nitrogen. Non-pliable plastic containers will not be exposed to liquid nitrogen, as they can explode at low temperatures. Liquid nitrogen will only be stored in the container in which it is delivered. This container will be left closed as much as possible to minimize the release of nitrogen gas into the air (nitrogen gas released by liquid nitrogen can displace oxygen, creating a suffocation hazard). It will only be used in well-ventilated areas of the laboratory.

Concentrated nitric acid will be handled with extreme caution. It will only be handled in a fume hood. When handling this acid, a lab coat, neoprene gloves, safety glasses, and a face shield will be worn at all times. These precautions will also be taken

when handling concentrated perchloric acid. In addition, perchloric acid will only be handled in a fume hood specifically designed for its use.

E.3 Physical Hazards

Electrical systems will not be “daisy-chained” (power strips will not be plugged into other power strips). In addition, the cloth used to block light from growth shelves will be breathable to prevent heat buildup. The temperature of these shelves will be monitored to ensure that temperatures never reach potentially hazardous levels.

Appendix F. Quality assurance and control

For all experiments, reagents used will be reagent grade or better. Concentrated acid reagents will be trace metal grade or better. In order to confirm the accuracy of measurements, all balances used in these experiments will be tested against standard weights. Pipettes will be tested for accuracy by comparing the mass of dd-H₂O dispensed to the expected mass for each volume. Class A volumetric glassware will be used to measure larger volumes within the recommended temperature ratings. A blank and a calibration curve verification will be tested for all instrumental analyses for every ten samples. The instrument will be recalibrated when conducting calibration curve verifications if the values measured are outside an acceptable range. A variation of up to 10 % from the known concentration will be considered acceptable for analyses of inorganic compounds. Where appropriate (i.e., ICP-MS measurements), a spiked sample will be included for every ten samples to check for matrix interference.

For tissue digests, 1 of each of the following checks will be taken through the digestion process for every ten samples digested to check for losses occurring due to the digestion procedure: one blank, one solution with a known concentration of element, and one sample containing a known mass of 1573a tomato leaves or 1547 peach leaves from the National Institute of Standards and Technology (NIST).

The pH probe will be calibrated with three pH buffer solutions before use. It will be confirmed that the millivolt reading at pH 7 is near 0 ± 25 mV and that the slope is within 90% of Nernstian. If the probe does not meet these standards, the electrode will be cleaned and the filling solution replaced before use. The EC probe will be calibrated before each use with solutions representative of the expected range of values for the measured

samples. If measurements fall outside the calibration range, a new calibration will be conducted before the samples are remeasured.

The *PcO6* stocks used for these experiments were created in 2016 by Dr. Astrid Jacobson and Dr. Anne Anderson from original (2003) freezer stocks checked for phenazine formation on rich LB medium. *P. protegens* Pf-5 (ATCC BAA-477), another beneficial soil bacterium, was purchased from American Type Culture Collection (ATCC) in June 2022 for its documented ability to produce chitinase (Loper et al., 2016). These stocks will be stored in a -80 °C freezer in 15% glycerol. When these stocks are defrosted, they will be observed to confirm that they are not gelatinous (which would indicate cell lysis). When preparing inoculation solutions, the approximate solution concentration will be checked using a spectrophotometer to measure optical density at the 600 nm wavelength. The measured values will be compared to previously measured spectrophotometer values correlated to colony-forming unit concentrations using serial dilutions. The inoculation solution will also be diluted by ten-fold serial dilutions, and three aliquots of 200 µL will from each dilution be placed on LB/TSA plates further to verify the concentration of *PcO6/Pp* Pf-5 in the solution. The plates will be checked each day after the samples are added, and the number of aliquots that have formed colonies will be recorded. At the end of each growth study for which inoculation with *PcO6/Pp* Pf-5 occurred, roots will be dabbed on LB/TSA plates and allowed to grow for three days to confirm that *PcO6/Pp* Pf-5 is present (indicating successful inoculation) and to confirm that no visible colonies of other microbes are present (which would indicate unintentional contamination).

Appendix G. Curriculum vitae

Li-Ting Yen

EDUCATION

<i>Ph.D. in Soil Science,</i> Utah State University, UT, USA	2020 - 2024
<i>Ph.D. in Environmental Science,</i> National Chung Hsing University, Taichung, Taiwan	2017 - 2024
<i>B.S. in Environmental Science,</i> National Chung Hsing University, Taichung, Taiwan	2013 - 2017
