This work demonstrates a design strategy to optimize antimicrobial peptides with an ideal balance of minimal cytotoxicity, enhanced stability, potent cell penetration and effective antimicrobial activity, which hold great promise for the treatment of intracellular microbial infections and potentially systemic anti-infective therapy.

Naturally occurring antimicrobial peptides (AMPs) serve as the first line of host defense against a variety of microbial infections. A large number of AMPs consisting of both natural and non-natural amino acids have been de novo designed. In the past, the majority of work has focused on sequence variation and structural optimization of single peptide chains to achieve a balance between antimicrobial efficiency and selectivity. Successful design has and will continue to advance topical application of AMPs in clinically relevant settings. However, for systemic antimicrobial therapy using AMPs, particularly for the targeting of intracellular microbial pathogens, new strategies are highly desirable to overcome the intrinsic limitations associated with single peptide chains. Such limitations include cytotoxicity, protease susceptibility (for α-peptides), poor cell penetration activity, and limited in vivo circulation half-life.

Peptide-based supramolecular assemblies represent an emerging and important class of biomaterials that have been extensively utilized in various biomedical fields, including drug delivery, vaccination, 3-D cellular scaffolds, and antimicrobial hydrogels. Supramolecular peptides are assemblies of monomeric peptides held together by non-covalent interactions to form discrete nanostructures or nanostructured networks. Compared to single peptide chains, these large-scale assemblies have a distinctive mode of self-assembly behavior above a certain assembly concentration (CAC). For all the peptides, tryptophan (W) was incorporated for accurate concentration measurement. The position of W was also found to influence the molecular nanofibers. (WK2(QL)6K2), 2 (WK3(QL)6K2), and 3 (K3W(QL)6K2), which are molecular nanofibers. The supramolecular nanostructure and stability can be tuned by adjusting the ratio between different blocks. The end products reflect an energetic balance between the intermolecular hydrogen bonding and hydrophobic interactions among the lysine residues. Scheme 1 shows a representative chemical structure of a MDP and its self-assembly into supramolecular nanostructures.

The peptide sequences are based upon previously designed multidomain peptides (MDPs) with a general formula of Kx(QL)yKz, which are cationic as well as amphiphilic. Unlike most AMPs that exist as a monomer prior to their binding with lipid membranes, MDPs can be formulated into soluble supramolecular nanostructures. The supramolecular nanostructure and stability can be tuned by adjusting the ratio between different blocks. The end products reflect an energetic balance between the intermolecular hydrogen bonding and hydrophobic interactions among the (QL) repeating units and electrostatic repulsion among the lysine residues. Scheme 1 shows a representative chemical structure of a MDP and its self-assembly into supramolecular nanostructures. Three peptides were used in the current study, MDP-1 (WK2(QL)yK2), 2 (WK3(QL)yK2), and 3 (K3W(QL)yK2), which are designed to form supramolecular assemblies above a critical assembly concentration (CAC). For all the peptides, tryptophan (W) was incorporated for accurate concentration measurement. The position of W was also found to influence the molecular secondary structure, supramolecular nanostructure, stability,
and the antimicrobial activity of MDP-2 and MDP-3, which have identical amino acid compositions.

Fig. S1 (ESI†) shows the circular dichroism (CD) spectra of all three peptides. The secondary structure of WK₂(QL)₆K₂ (MDP-1) showed predominantly beta sheets as characterized by a single minimum peak at 216 nm. Adding an additional lysine residue led to denaturation of ordered beta sheets into random coils more likely at both termini. For WK₃(QL)₆K₂ (MDP-2), fitting of the CD spectrum gives rise to 41.4% beta sheets, 40% random coils and the rest being alpha helices. However, for K₃W(QL)₆K₂ (MDP-3) with the same number of lysine residues as WK₂(QL)₆K₂, switching the three N-terminal lysine residues with W led to a restoration of beta sheet structure. This is largely due to the creation of the additional “KW” hydrophobic–hydrophilic repeating unit following the (QL)₆ domain at the N terminus so as to increase the driving force for beta sheet formation.

As shown in Fig. 1, all three peptides are capable of self-assembly into supramolecular nanofibers above their CACs. The CAC was determined by the previously established fluorescence self-quenching method where the fluorescence intensity of fluorescein labeled peptides was measured as a function of peptide concentration.⁹ Due to the formation of supramolecular assemblies, the fluorophores are in spatial proximity such that the change of the fluorescence intensity falls off the linear range and the cross point between the two regions is defined as the CAC. The CACs for MDP-1, 2, and 3 are 0.87 μΜ, 1.24 μΜ and 1.37 μΜ, respectively (Fig. S2, ESI†).

The nanostructure formation is further confirmed and quantified in more detail using small-angle X-ray scattering (SAXS). The data were fitted on an absolute intensity scale using a form factor of a regular platelet, i.e. long filaments, described by the three lengths, \(a < b < c\). The SAXS data (Fig. S3, ESI†) suggest rather well-defined fibers in solution with lengths \(c\) of 40–50 nm, width \(b\) of 5.8, 6.7, and 5.7 nm, and height \(a\) of 4.8, 4.7, and 2.7 nm for WK₂(QL)₆K₂, WK₃(QL)₆K₂, and K₃W(QL)₆K₂, respectively. The fitting was greatly improved by incorporating a Gaussian distribution function describing a dispersion in \(a\) of ~28%, 35%, and 20% respectively. The difference in the fiber dimensions was presumably due to the “edge” effect of the lysine residues adopting different molecular secondary structures. A non-canonical geometric model and fitting methods will be developed to elucidate the fine structure and packing of these nanofibers for future studies.

The cytotoxicity of the three MDPs and melittin, a naturally occurring AMP, was evaluated using primary mouse bone marrow-derived monocytes (BMDMs). After 24 h of incubation with different peptides at concentrations of 1, 5, and 20 μΜ, released lactate dehydrogenase (LDH), an indicator of cell death, was quantified by ELISA (Fig. 2a and b). The percent cytotoxicity was calculated relative to the manufacturer-provided positive cell lysis control. Release of LDH from untreated BMDMs served as a negative control and this amount was subtracted from the positive control and peptide-treated groups. As shown in Fig. 2a, for all three MDP peptides, it was observed that an increase of peptide concentration above 1 μΜ abolished the MDP’s cytotoxicity. At first, this observation is quite surprising as it is contrary to dose-dependent relationships between concentration and cytotoxicity. Although the detailed molecular mechanism is unknown, we hypothesized that at low peptide concentrations, monomers/oligomers exist predominantly and they have the ability to insert into lipid membranes and cause membrane disruption and LDH leakage.

Such action is reminiscent of the working mechanism of most natural and synthetic single chained AMPs against both bacteria and mammalian cells. However, as peptide concentration increases, monomers/oligomers undergo self-assembly into supramolecular nanofibers. MDPs, having the characteristic of amyloid-like peptides, are more likely to follow the typical autocatalytic growth of nanofiber formation.⁸,¹⁰ Monomers/oligomers will be quickly consumed and organized into supramolecular nanofibers. MDP fibers are relatively short (below 100 nm) due to the electrostatic repulsion so as to remain soluble in aqueous buffer, whereas typical amyloid-like peptides form elongated fibers on the order of at least micrometers in length and eventually precipitate out of the solution. Reduced cytotoxicity was mainly attributed to the formation of these supramolecular,
short, soluble nanofibers which have been found to be more membrane permeable\textsuperscript{26} and therefore less cytotoxic. In contrast to the fiber-forming MDPs, as shown in Fig. 2h, melittin as a monomeric AMP, is highly cytotoxic and exhibits a dose-dependent effect. In Fig. 2c the effect of exposure to 1 and 20 μM MDP on the total number of cells per tissue culture well is presented. In accord with the LDH release results, exposure to 1 μM, but not 20 μM MDP resulted in a significant decrease in cell numbers compared to untreated controls.

Recently, antimicrobial supramolecular assemblies have been designed based on the self-assembly of terephthalamide core bis-urea containing cationic polymers and small molecules.\textsuperscript{4,11} Current work on the design of antimicrobial supramolecular peptides echoes these previous efforts for the construction of highly effective antimicrobial supramolecular biomaterials. Successful design of antimicrobial peptides beyond the molecular level will also complement conventional AMPs design and provide unique opportunities for treating intracellular bacterial infections, which is another topic being studied in our lab and will be reported separately.

The primary goal of this work is to demonstrate the antimicrobial effect of the designed supramolecular MDPs on bacterial viability and understand the influence of various physical and chemical parameters on antimicrobial efficiency. The antimicrobial activities of WK\textsubscript{2}(QL)\textsubscript{6}K\textsubscript{2}, WK\textsubscript{3}(QL)\textsubscript{6}K\textsubscript{2}, and K\textsubscript{3}W(QL)\textsubscript{6}K\textsubscript{2} were tested against both gram negative bacteria, Escherichia coli and Pseudomonas aeruginosa and gram positive bacteria, Staphylococcus epidermidis and S. aureus. Peptides were co-incubated with each bacterial species for 18 h (for \textit{E. coli} and \textit{P. aeruginosa}) or 36 h (for \textit{S. aureus} and \textit{S. epidermidis}) and the UV absorbance at 600 nm was measured for the calculation of minimum inhibitory concentration (MIC) values. As shown in Table 1, based on the MIC results, WK\textsubscript{3}(QL)\textsubscript{6}K\textsubscript{2} was found to have the most effective antimicrobial activity, followed by K\textsubscript{3}W(QL)\textsubscript{6}K\textsubscript{2} and WK\textsubscript{2}(QL)\textsubscript{6}K\textsubscript{2}.

Different antimicrobial effects were also confirmed by a bacterial killing efficiency study where 99% of gram negative bacteria were killed by WK\textsubscript{3}(QL)\textsubscript{6}K\textsubscript{2}, 98% by K\textsubscript{3}W(QL)\textsubscript{6}K\textsubscript{2}, and less than 40% by WK\textsubscript{2}(QL)\textsubscript{6}K\textsubscript{2} (Fig. S4, ESI\textsuperscript{†}). The same trend of killing activity was observed with gram-positive bacteria. Such order of activity inversely correlates with the peptides’ tendency to form beta sheets and thus the stability of the supramolecular nanofibers. We believe that charge density plays a minimal role in the antimicrobial action of these supramolecular assemblies. MDP-2 and 3 have the exact same residue composition and charge density, yet they display dramatically different antimicrobial activities. A parallel study in our lab showed that D-amino acid substitution for the lysine residues on WK\textsubscript{3}(QL)\textsubscript{6}K\textsubscript{2} slightly reduced beta sheet content and nanofiber integrity (data not shown). However, the antimicrobial efficiency was dramatically improved for the \textit{d}-peptide although both \textit{d} and \textit{l} peptides contain the same number of charged residues. Additionally, the residual peptide monomer is not likely to contribute to the different antimicrobial activities observed since the CACs are quite low. More importantly, negligible amounts of monomers are expected in solution due to the consumption of monomers/oligomers in the process of autocatalytic growth of the nanofibers. Indeed, it is the intermolecular interactions between MDP building blocks that plays a key role in the membrane activity of these supramolecular assemblies and directly influences both primary cell viability and antimicrobial activity.

Scanning electron microscopy (SEM) was used to visualize the morphological change in bacteria with the addition of different MDPs. All three peptides were incubated with bacteria for 1 h before SEM imaging. Fig. S5 (ESI\textsuperscript{†}) shows the morphological changes in \textit{E. coli} and \textit{S. aureus} when exposed to peptides. Both WK\textsubscript{3}(QL)\textsubscript{6}K\textsubscript{2} and K\textsubscript{3}W(QL)\textsubscript{6}K\textsubscript{2} caused bacterial cell damage and confirmed the mode of antimicrobial activity through membrane disruption. WK\textsubscript{2}(QL)\textsubscript{6}K\textsubscript{2}, however, showed negligible membrane disruption as compared to control.

A significant concern of peptides composed of natural amino acids is their protease susceptibilities. Peptides consisting of non-natural amino acids, such as \textit{d}-amino acids,\textsuperscript{12} \textit{β}-amino acids,\textsuperscript{12,27} and \textit{γ}-AA amino acids,\textsuperscript{28,29} and peptoids\textsuperscript{14} have been successfully designed and synthesized to solve the issue of protease stability, although the cost of their production may be prohibitive for general widespread use. More recently, peptide nanofilaments and nanobeacons were shown to have different enzymatic degradation rates.\textsuperscript{15} Consistent with this recent discovery, our results demonstrate that the supramolecular assembly can be used as another effective approach to improve the protease susceptibilities of antimicrobial peptides containing naturally occurring \textit{z}-amino acids. As shown in Fig. 3, peptides without enzymatic treatment were eluted as a major singlet at ~17 min. The three MDPs showed differing proteolytic stability upon incubation with two common enzymes, trypsin and chymotrypsin for 18 h and the degradation products of each peptide were monitored by HPLC.

For WK\textsubscript{3}(QL)\textsubscript{6}K\textsubscript{2}, a larger fraction of materials remained intact in the presence of these enzymes. With the addition of a single lysine residue, WK\textsubscript{3}(QL)\textsubscript{6}K\textsubscript{2} exhibited dramatically

diminished stability as demonstrated by a HPLC peak shift upon enzymatic treatment. However, the enzymatic stability was retrieved for K,W(QL),K , which has a larger fraction of beta sheets and therefore greater supramolecular stability. Quantitative results of the percentage of degradation are summarized in Table S1 (ESI†). The resistance to proteolytic degradation observed here strongly correlates with the peptides’ ability to self-assemble into supramolecular nanostructures. The refined nanostructures are likely to create steric hindrance for the proteases to access the active reaction sites thereby reducing degradation. Additionally, in the presence of serum, MDP-1 and MDP-2 with higher beta sheet contents are more stable than MDP-3 with reduced beta sheet character (Fig. S6, ESI†). A summary of the molecular structures and biological activities of MDP nanofibers was shown in Fig. S7 (ESI†). It can be envisioned that through co-assembly of different sequenced MDNs, an ideal balance between supramolecular character (Fig. S6, ESI†) and biological activities of MDP nanofibers was shown in Fig. S7 (ESI†). It can be envisioned that through co-assembly of different sequenced MDNs, an ideal balance between supramolecular character (Fig. S6, ESI†) and biological activities of MDP nanofibers was shown in Fig. S7 (ESI†).

In conclusion, supramolecular peptide assemblies have been demonstrated to be a viable platform for the design and synthesis of AMPs that can strike a balance between structure, stability, cytotoxicity, and antimicrobial activity could be achieved.
