EVALUATION AND MANAGEMENT OF DIETARY HABITS IN
JAPANESE RENAL STONE FORMERS

Abstract

To elucidate the relationship between the formation of kidney stones and diet, we carried out a dietary investigation in patients with urinary tract stones. Dietary intakes were estimated for 36 patients (24 men, 12 women) with calcium stones, and compared with the official dietary requirements for the Japanese.

Total protein intake, animal protein intake and animal protein ratio were significantly higher for patients with stones in both men and women. Dietary salt intake was significantly higher for male patients and the total group. Dietary calcium and carbohydrate intakes were significantly lower for patients with stones in men and the total group, and tended to be lower for female patients.

As a result of dietary guidance, the intakes of total protein, animal protein and salt were markedly reduced. The animal protein ratio was also lowered. Calorific intake and the dietary intakes of carbohydrate, fat and salt were reduced, too. However, the dietary calcium intake did not change. Chemical analysis of 24 hour-urine revealed that the excretion of urea nitrogen was reduced, which reflected the decrease in protein intake produced by the dietary regimen. The excretions of urate and oxalate also tended to decrease.

Key Words: Kidney stone, calcium oxalate, dietary habits, dietary management, calcium intake, protein intake, salt intake, urinary calcium, urinary oxalate, urinary urate.

Introduction

The incidence of renal stones rapidly rose after the second world war in western countries [22], and slightly later, in Japan too [20], where the incidence of nephrolithiasis has increased approximately 3 times compared to that before the war. Even in the recent 10 years, from 1975 to 1985, the 35% increase had been observed in the risk of suffering from urolithiasis at some time in one’s life. But the incidence is still half of that in the U.S.A. [27]. The change of life-style, especially that of dietary habit, has been suggested as the causative factor of the upsurge in the incidence of nephrolithiasis [25]. However, according to Fellström et al. [6], there seem to be only marginally different dietary habits between stone formers and carefully matched control subjects. To elucidate the significance of diet in the formation of renal stones, we investigated the effects of the types of food taken by patients with calcium stones, and studied the potential effect of dietary counseling.

Subjects and Methods

A total of 36 patients (24 men, 12 women) participated in the study, who had calcium stones without apparent predisposing conditions such as primary hyperparathyroidism and renal tubular acidosis. Patients with renal failure or urinary tract infection were excluded. Men were 20 to 78 years of age (mean 44 years; standard deviation, SD: 13 years), and women were 20 to 67 years (mean 39 years; SD: 13 years), with the mean and SD for the total group at 42 years and 13 years, respectively. Patients in their 20s to 40s accounted for 79% of the males and 83% of the females.

Stones were removed by extracorporeal shock wave lithotripsy (ESWL; EDAP LT-01) on an outpatient basis in most patients. In these cases, the patients were studied after 1 month or later when they were restored to ordinary daily life. When patients were hospitalized or underwent an open operation, the study was performed after 3 months or later. Urine was collected on a 24-hour basis, and the dietary intake was investigated by the staff of the nutrition department of our institute.

The values of nutrients shown here represent the mean of 3-day measurements. Dietary requirements were calculated from the 4th version of "Recommended Dietary Allowances for the Japanese" [9] for the subjects on the basis of their sex, age, height and physical activity. The animal protein ratio was placed at 45% in consideration of the recommended value, which was 40 to 45% [1]. This was followed by dietary counseling for 16 men (41 ± 10 years) and 11 women (43 ± 16 years), a total of 27 subjects (42 ± 12 years). The patients were instructed to use the Recommended Dietary Allowances for the Japanese as their goal. The contents of their diet were re-investigated 2 months after the completion of dietary counseling and 24-hour-urine was collected from 19 of the subjects.

The collection of 24-hour-urine was done at the outpatient clinic. For the measurement of calcium and

oxalate, urine was collected in a vessel containing 100 ml of 1.2 N hydrochloric acid. For the measurement of other components, urine was collected in a vessel not containing preservatives. Urea nitrogen, creatinine, calcium, magnesium, phosphorus, uric acid, and sodium and potassium in the urine were measured with an auto-analyzer (Hitachi Model 705, Tokyo, Japan). The excretion of ≥ 300 mg calcium/day for men or ≥ 250 mg calcium/day for women was defined as hypercalciuria [5]. The excretion of ≥ 800 mg uric acid/day for men or ≥ 750 mg uric acid/day for women was defined as hyperuricosuria [26]. Oxalate was determined according to the method of Frazer et al. [10]. Briefly, 20 ml urine, centrifuged to remove the solid matter, was adjusted to pH 4.5 with NH₄OH solution. To this urine, 0.4 ml of 2mg/ml Na₂C₂O₄ solution and 0.4 ml of 100 mg/ml CaCl₂ solution were added. This mixture was heated to 100°C, then cooled to room temperature, and its pH was readjusted to 4.5 with a solution of NH₄OH or H₂SO₄. It was then centrifuged. The precipitate was washed 3 times with 6 ml saturated solution of CaC₂O₄ in water, and dissolved in 1 ml of 1 N H₂SO₄ by heating at 60°C, for 5 minutes. Subsequently, 4.0 ml distilled water was added to this solution, then the solution was further diluted 25 times with water, and its calcium content was determined with atomic absorption spectrophotometer.

Results

Comparison of the dietary intakes of calcium stone patients with the dietary requirements for the Japanese (Table 1) revealed that total protein intake, animal protein intake, and animal protein ratio were markedly higher for patients with calcium stones in men, women or the total group. Dietary salt intake was significantly higher for male patients and the total group, and tended to be higher for female patients. Dietary carbohydrate and calcium intakes were lower for male patients and the total group, and a similar tendency was detected in women. Dietary fat intake was higher for female patients, but not for male patients.

Fig. 1 shows the total protein intake of individual patients as compared with the dietary requirements for the Japanese. In nearly all patients, the intake exceeded the requirements.

The dietary calcium intake, which is of particular interest, was significantly lower than the requirement in the total group and in men, and a similar tendency was noted in women (Fig. 2). Table 2 shows the dietary intakes before and after dietary counseling. As a result of the counseling, total protein, animal protein and salt intakes were markedly reduced. The animal protein ratio was also reduced. In addition, calorie, carbohydrate, and fat intakes, were reduced as well, but no change was observed in calcium intake.

Fig. 3 shows changes in individual total protein intake. Dietary protein intake was reduced as a result of the dietary counseling in men, women and the total group.

Table 3 shows the urinary excretions of calculi-related substances. The excretion of urea nitrogen was reduced as a result of dietary counseling. The uric acid and oxalate excretions also tended to, but did not significantly, decrease. The calcium and phosphorus excretions did not change.

Fig. 4 shows the individual urinary excretion of uric acid before and after dietary counseling. It tended to decrease after counseling.

**Discussion**

Unlike struvite or cystine stones [16], it is well known that the formation of calcium stones is related to diet. Particularly, evidence from both long-term [28] and short-term [24] studies shows that an increase in animal protein intake leads to a rise in the incidence of renal stones. Meanwhile, in the comparison of protein intake between patients with stones and the control matched for socioeconomic status, no difference was detected between groups as to intake [6]. The present study confirmed the contention of former group by revealing that patients with calcium stones ingested more total as well as animal protein. The total protein intake, animal protein intake, and animal protein ratio in patients with stones, whether male or female, were well above the requirements for the Japanese. Urinary citrate, a low molecular weight inhibitor, is known to be involved in the physicochemistry of stone formation and

![Graph](image)

**Figure 2.** Comparison of calcium intake by stone patients and nutrient requirements of Japanese.

known to be affected by diet. In our investigation, neither urinary citrate nor high molecular weight inhibitors were measured.

Urinary calcium is certainly related to the formation of stones. In the present study, however, when patients with stones were divided into hypercalciuric and normocalciuric groups, and the two groups were compared with respect to protein intake, the total protein intake tended to be higher for the normocalciuric group. Animal protein intakes in 2 groups were almost the same. This result, though its implications are unclear, differs from the findings of Iguchi et al. [14].

When patients were divided into hyperuricosuric and normouricosuric groups, protein intake was higher for the former group. Then, dietary counseling significantly reduced dietary protein intake, which resulted in a decrease in the urinary excretion of uric acid. This might suggest that an increase in urinary uric acid is of greater significance in this population. The importance of urate in urine has already been reported [4]. It is said to decrease the activity of urinary inhibitors and promote the epitaxial growth of calcium oxalate crystal [7, 15]. Grover et al. [12] also re-emphasized the promotive role of hyperuricosuria in urolithiasis.
Dietary habits in renal stone formers

Before

nutrient requiremet

of Japanese

After

Figure 3. Change of total protein intake resulting from dietary counseling.

High dietary salt intake is said to result in an increase in the urinary excretion of calcium [21]. Our results from the hypercalciuric (n = 7) and normocalciuric (n = 29) groups showed that the urinary excretion of sodium tended to be higher in the former (6364 ± 1943 mg versus 5017 ± 1863 mg, not significant).

Iguchi et al. [14] reported that calcium intake in patients with stones fell short of the calcium requirement for the Japanese. This was confirmed by our study. We previously reported that the combined administration of calcium and citrate preparations reduced urinary oxalate without increasing urinary calcium [18, 19]. Dietary advise based on the same idea should produce the same effect. This involves reducing protein intake and eating more sea-weed and vegetables, while increasing calcium intake. Our study may provide some interesting suggestions in this respect. That is, calcium could be safely administered to patients with stones because the dietary calcium intake is low in these patients.

References

Dietary habits in renal stone formers

W.G. Robertson: There was a 20% reduction in animal protein consumption by stone formers after dietary advice, yet uric acid hardly fell. What dietary constituents were reduced during the advice period? Was there only a reduction in the consumption of eggs and dairy produce but not in meat, fish, and poultry?

J. Costello: The authors refer to a decrease in protein intake decreasing uric acid excretion and conclude from this the significance of uric acid in stone formation. However, urinary uric acid did not decrease significantly (Table 4). How can these conclusions be supported by the authors' data?

Authors: We think that all types of proteins were reduced after dietary advice. Although the decrease of uric acid was not significant, it did decrease and the decrease would become significant if a study with a larger number of patients could be done.

J. Costello: Was protein intake correlated with urinary oxalate excretion before or after dietary counseling?

Authors: Protein intake did not correlate with urinary oxalate excretion before or after dietary counseling.

J. Costello: There was no control group studied that did not receive dietary counseling. This would have been most helpful.

W.G. Robertson: In this paper, you have compared the actual intakes of a number of nutrients in stone formers with recommended daily intakes for these individuals. How do these data compare with the intakes of these nutrients in normal control subjects?

Authors: We would like to do a case-control study as the next step.

P.P. Singh: Urinary ascorbic acid adds extra oxalate during collection of urine in 1.2 N HCl. I have not gone through the method of Fraser and Campbell (text reference 10) for oxalate determination but I suspect that ascorbic acid might be contributing additional oxalate during precipitation. Authors should check if this is the reason for high oxalate values in their patients.

Authors: We checked the pH of 24-hour urine prior to measurement of oxalate and found that the pH was below 2.0. Therefore, it seems that ascorbic acid does not contribute additional oxalate.

P.P. Singh: In the western population calcium intake has also gone up along with animal protein owing to increased intake of non-vegetarian foods and dairy products, while in the Japanese population the consumption of these foods has gone up several fold and has come up almost at par with western subjects, but their calcium intake remains relatively much lower. Neither Iguchi et al. (text reference 14) nor the present authors have explained the reasons for that. The authors should, therefore, include the names of foods responsible for low calcium levels.

Authors: Animal protein does not contain large amounts of calcium. Japanese people take much less milk and dairy products than western people. We think that that is one of the reasons why calcium intake in Japanese is less than in western people.
