The lily leaf beetle (LLB) (Coleoptera: Chrysomelidae) is an important pest from Eurasia that threatens native and cultivated true lilies (Lilium spp.) and fritillaries (Fritillaria spp.). It is also known as the red lily leaf beetle or scarlet lily beetle. LLB was first reported in North America in Montréal, Canada, in 1945 and in the U.S. in 1992 in Massachusetts, likely arriving via European shipments of lily bulbs. LLB has been detected in nine of the 10 Canadian provinces and 14 U.S. states, including the New England states, Pennsylvania, Wisconsin, Minnesota, and Washington (EDDMapS, 2021). Based on LLB's native distribution and habitat suitability, it is likely capable of establishing throughout most of the U.S. where plants in the Liliaceae family occur (Freeman et al., 2020), which includes Utah. In its native range, populations are kept under control by native parasitoids and predators that have coevolved with LLB. In the northeastern U.S., wasp parasitoid specialists have been successfully introduced for control of LLB.

**Quick Facts**

- Lily leaf beetle (LLB) is an introduced pest from Eurasia that causes damage to plants in the Liliaceae family.
- Native and cultivated Lilium and Fritillaria species are sensitive to attack, including rare and endangered species.
- Daylilies (Hemerocallis spp.) are not at risk for attack.
- This is the only Lilioceris beetle known in North America. It is not known to occur in Utah.
- LLB can cause economic and aesthetic losses for commercial lily growers and home gardeners.
- The larval stage causes the most damage, but both adults and larvae can completely defoliate host plants without control measures in place.
- In its native range, populations are kept under control by native parasitoids and predators that have coevolved with LLB. In the northeastern U.S., wasp parasitoid specialists have been successfully introduced for control of LLB.

**INTRODUCTION**

The lily leaf beetle (LLB) (Coleoptera: Chrysomelidae) is an important pest from Eurasia that threatens native and cultivated true lilies (Lilium spp.) and fritillaries (Fritillaria spp.). It is also known as the red lily leaf beetle or scarlet lily beetle. LLB was first reported in North America in Montréal, Canada, in 1945 and in the U.S. in 1992 in Massachusetts, likely arriving via European shipments of lily bulbs. LLB has been detected in nine of the 10 Canadian provinces and 14 U.S. states, including the New England states, Pennsylvania, Wisconsin, Minnesota, and Washington (EDDMapS, 2021). Based on LLB's native distribution and habitat suitability, it is likely capable of establishing throughout most of the U.S. where plants in the Liliaceae family occur (Freeman et al., 2020), which includes Utah. In its native range, LLB outbreaks are rare, but significant losses to lily crops are currently occurring where LLB has been introduced, including the Netherlands and Great Britain. LLB adults are strong fliers which enables them to disperse to new locations, but this pest can also be introduced by hitchhiking on unsuspected host material that includes movement of potted Lilium plants. LLB is not known to occur in Utah. If you suspect LLBs in Utah, please contact the Utah Plant Pest and Diagnostic Lab.

**DESCRIPTION**

Adults (Figs. 1 to 3) are from 1/4 inch to 3/8 inch (6 to 9.5 mm) in length. The thorax and abdomen are shiny and scarlet red in color with tiny dimples, whereas the head, legs, antennae, and undersides are black. Adults readily drop from the host plant when disturbed and play dead as they lay upside down on the ground surface. They make a shrill sound (stridulate) when squeezed (Liesch & Johnson, 2020).

Larvae (Fig. 4) are plump, squishy, and sluglike, with black heads and orange, yellow, brown, or rarely green bodies. They cover their bodies with their own excrement and can resemble slimy greenish-brown slugs or a moving pile of animal feces (Liesch & Johnson, 2020). Larvae can reach up to about ½ inch (12 mm) in length when mature.

Pupae are bright orange and encased in a whitish silk-like cocoon about 5/16 inches (9 mm) in length and made from saliva (Fig. 5).

Eggs are tiny and irregularly shaped and about 1/10 inch in length. They are bright scarlet red to reddish-orange (Fig. 6) and darken as they mature.
Adults and larvae can cause economic losses as they feed on plants in the Liliaceae family (true lilies), including both native and cultivated lily varieties (Lilium spp.) such as Turk’s cap lily (L. superbum), Easter lily (L. longiflorum), Asiatic lily (L. asiatica), Oriental lily (L. spp.), tiger lily (L. lancifolium), and their hybrids, as well as fritillaries (Fritillaria spp.), giant lily (Cardiocrinum giganteum), Canada mayflower (Maianthemum canadense), and cultivated onion (Allium cepa). Adults can be found resting or feeding on non-Liliaceae plants such as Solomon’s seal (Polygonatum spp.), lily of the valley (Convallaria majalis), various hosta species (Hosta spp.), bittersweet nightshade (Solanum dulcamara), potato (Solanum spp.), hollyhock (Alcea spp.), flowering tobacco (Nicotiana spp.) and Smilax spp., but LLBs neither reproduce on these plants nor cause significant damage to them. Daylilies (Hemerocallis spp.), canna lilies (Canna spp.) and calla lilies (Calla spp.) are not true lilies and are not at risk for attack. LLB could potentially affect Utah’s state flower, the sego lily (Calochortus nuttallii), and Utah’s native yellow fritillaries (F. pudica) if its range expands into Utah forests (Freeman et al., 2020).

**DAMAGE SYMPTOMS**

Adults and larvae create irregular holes and notches in leaves, stems, and developing buds of host plants as they feed, and severe feeding damage can result in destroyed flowers and severe plant defoliation (Figs. 7 and 8). Early summer attacks can result in undersized bulbs that may not flower the following year (RHS, n.d.), and weakened plants may become more susceptible to pathogens such as Botrytis leaf blight and lily gray mold (Botrytis elliptica).

**PLANT HOSTS**

Adults and larvae can cause economic losses as they feed on plants in the Liliaceae family (true lilies), including both native and cultivated lily varieties (Lilium spp.) such as Turk’s cap lily (L. superbum), Easter lily (L. longiflorum), Asiatic lily (L. asiatica), Oriental lily (L. spp.), tiger lily (L. lancifolium), and their hybrids, as well as fritillaries (Fritillaria spp.), giant lily (Cardiocrinum giganteum), Canada mayflower (Maianthemum canadense), and cultivated onion (Allium cepa). Adults can be found resting or feeding on non-Liliaceae plants such as Solomon’s seal (Polygonatum spp.), lily of the valley (Convallaria majalis), various hosta species (Hosta spp.), bittersweet nightshade (Solanum dulcamara), potato (Solanum spp.), hollyhock (Alcea spp.), flowering tobacco (Nicotiana spp.) and Smilax spp., but LLBs neither reproduce on these plants nor cause significant damage to them. Daylilies (Hemerocallis spp.), canna lilies (Canna spp.) and calla lilies (Calla spp.) are not true lilies and are not at risk for attack. LLB could potentially affect Utah’s state flower, the sego lily (Calochortus nuttallii), and Utah’s native yellow fritillaries (F. pudica) if its range expands into Utah forests (Freeman et al., 2020).

**LIFE HISTORY**

LLB adults overwinter and emerge in early spring when the first lily leaves appear and begin actively feeding on foliage and searching for a mate. After feeding for 2 to 3 weeks, mated females lay from 2 to 16 eggs at a time (averaging about 12) in one or more rows parallel to a leaf vein on the underside of leaves and on flower buds or open flowers. Feeding and egg production continues until late summer or as long as fresh lily leaves are available. The eggs hatch in 6 to 7 days at 72 °F (22 °C), and the developing larvae typically cover their bodies with a thick protective barrier of frass (insect feces) as they feed, giving them the appearance of mobile piles of excrement. Larvae undergo four larval stages (instars) over 2 to 3 weeks. First instar larvae typically begin feeding as a group on a leaf’s under surface and gradually move to the upper surface...
and buds as they develop. The later instars feed on the entire leaf, beginning at the margin of lower leaves and moving upwards on the plant as new growth occurs. Leaves, flowers, stems, and buds can be consumed, and both adults and larvae can be found feeding together. Mature larvae drop to the ground and use saliva and soil to build a cocoon and pupate in the soil, and the new adults typically emerge 2 to 3 weeks later in summer to feed before finding overwintering sites. Adults overwinter in the fall in soil, litter, or debris, not necessarily near host plants. One generation occurs per year (univoltine). Adults can live for several years, and each female can lay from 250 to 450 eggs in her lifetime. Adults can fly long distances to locate host plants, preferring areas that are protected, shaded, cool, and moist. They can be found on lilies throughout the growing season (CABI, 2020; Liesch & Johnson, 2020; Valerio, 2016).

**MONITORING**

Monitor host plants throughout the growing season for the presence of adults, larvae, eggs, and feeding damage. Check plants for adult LLBs beginning in spring when lilies and fritillaries emerge. Look for eggs on the underside of leaves beginning in April and frass-covered larvae in midsummer. When you see adults on a plant, turn over its leaves and inspect for rows of eggs. If you suspect LLB in Utah, contact the [Utah Plant Pest Diagnostic Lab](https://www.utahpests.usu.edu).

When looking for LLBs, keep in mind that Utah is home to some native insects that have a similar appearance (Fig. 9). Such lookalikes include the red-femured milkweed beetle (Tetraopes femoratus), which feeds exclusively on milkweed and can also stridulate; the red flat bark beetle (Cucujus clavipes), which feeds on insects inside trees; a blister beetle (Nemognatha lurida), which feeds on thistle and composites; and the boxelder bug (Boisea trivittata), which is a common native species in Utah.

Fig. 9. LLB lookalikes in Utah include (left to right) the red-femured milkweed beetle, the red flat bark beetle, a blister beetle, and adult and immature boxelder bugs.

**MANAGEMENT**

Currently, the most practical approaches for controlling LLB are to prevent them from occurring in the first place and eradicate individuals before they spread to new areas. LLB has not been detected in Utah, so there is no current need for control of this insect. Since all control options rely on proper identification of the pest species, please contact the [Utah Plant Pest Diagnostic Lab](https://www.utahpests.usu.edu) if you suspect LLB in Utah. The following content is for informational purposes.

**Cultural Control**

- **Handpick individuals from plants.** Handpicking adults, larvae, and eggs is an effective means of reducing LLB damage. As described in the “Monitoring” section, begin searching for LLBs in April and continue throughout the growing season, and check the underside of leaves for egg masses, especially when adults are present. Since the larvae cover themselves with insect feces, consider wearing gloves as you remove them from host plants.

- **Choose resistant or tolerant plants.** Nearly all lily species and cultivars are susceptible to LLB. Choose resistant plants if LLB has been detected in your area. Asiatic hybrids have shown susceptibility to LLB, while some Oriental lilies and hybrids such as *Lilium henryi* ‘Madame Butterfly’, *L. speciosum* ‘Uchida’, L. ‘Black Beauty’, *L. regale*, and L. ‘Golden Joy’ have shown some resistance (Murray, et al. 2014; Stack et al., 2009). The lily ‘Defender Pink’ is advertised as LLB tolerant (RHS, n.d.; Salisbury et al. 2009).

**Biological Control**

There are no known effective native enemies of LLB in North America, but three species of tiny European parasitoid wasps that are specific to the genus *Lilioceris* have been successfully introduced in the northeastern U.S.: *Tetrastichus setifer*, *Lemophagus errabundus*, and *Diaparsis jucunda* (Tewksbury et al., 2017). These wasps lay eggs inside LLB larvae, and the developing wasps use their LLB hosts as both food and shelter (Fig. 10). The parasitized LLB larva will drop to the ground to pupate, and in the spring, the wasp emerges from the body of its dead host (Valerio et al., 2016). Currently, these parasitoids are not known to occur in Utah. A related parasitoid wasp, *Tetrastichus julis*, occurs in our state and targets a close relative of LLB, the invasive cereal leaf beetle (*Oulema melanopus*) (Evans, 2018), but it is not known to attack LLB (Kher et al., 2013).

In areas where these LLB parasitoids are known to exist, minimize mulching of lily beds and avoid digging up lily bulbs. Soil is a better shelter for overwintering parasitoids than mulch, so in areas where these parasitoids exist, avoid disturbing the soil to encourage their success, especially in private gardens (CABI, 2020; Tewksbury et al., 2017; Valerio et al., 2016).

**Fig. 10.** LLB larvae being parasitized by *D. jucunda* (left) and *T. setifer* (right).
Chemical Control

Azadirachtin (neem oil) and insecticidal soaps have shown some control of LLB when applied every 5 to 7 days after egg hatch. Systemic insecticides, such as imidacloprid, may provide effective control as a foliage spray or soil drench, depending on the label instructions, but note that imidacloprid and other insecticides must not be applied to plants in bloom or when bees are active. Contact insecticides that are effective against larvae contain the active ingredients permethrin, cyhalothrin, deltamethrin, or pyrethrin (Saeed, 2017; Smith, 2013). In general, insecticides with shorter persistence are less damaging to nontarget species than those with longer persistence and/or systemic action. If chemical control is warranted, give preference to the less toxic chemicals such as insecticidal soaps and azadirachtin, and apply late in the day or early in the morning when bees are not active.
