3 31 Abstract
4

5 32 Although sampling the five tallest young aspen in a stand is useful for detecting the occurrence
6
7 33 of any aspen recruitment, this technique overestimates the population response of aspen to wolf
8
9 34 reintroduction. Our original conclusion that random sampling described a trophic cascade that
10
11 35 was weaker than the one described by non-random sampling is unchanged.

16
17 37 Main Text
18

19 38 Understanding trophic cascades (indirect effects of predators on plants and abiotic processes)
20
21 39 requires information about their occurrence and strength. A basic metric of trophic cascade
22
23 40 strength in the study of wolves, elk, and aspen in northern Yellowstone National Park has been
24
25 41 the annual change in browsing and height of young aspen following wolf reintroduction.
26
27 42 Knowledge about these annual changes has been based mainly on three time series that were
28
29 43 built from one or two years of sampling the three or five tallest young aspen within a stand and
30
31 44 retrospectively inferring past browsing and height using potentially inaccurate plant architecture
32
33 45 techniques (reviewed in Brice *et al.* 2022).
34
35
36
37
38
39

40 47 Ripple & Beschta (2007) pioneered the ‘five tallest’ technique (hereafter, 5T sampling), and they
41
42 48 described it as a “limitation” because “data are only representative of the first recovering aspen
43
44 49 (5 tallest per [stand]) and not an estimate of the aspen population response across Yellowstone’s
45
46 50 northern winter range” (Ripple & Beschta 2007:518). Kauffman *et al.* (2013) further elaborated
47
48 51 that “choosing the five tallest individuals for an evaluation of stand-level height and growth
49
50 52 is...inherently biased.” Our study quantified the extent of this bias, revealing, for example, that
51
52 53 5T sampling overestimated regeneration of overstory aspen by a factor of 4-7 compared to
53
54
55
56
57
58
59
60

1
2
3 54 random sampling (Brice *et al.* 2022: Figure 5). We concluded that 5T sampling overestimated
4
5 55 the aspen population response to wolf reintroduction, confirming previous concerns about its
6
7
8 56 limitations.

9
10 57
11
12 58 In their Comment, Painter *et al.* (2023) (hereafter Painter *et al.*) do not challenge our conclusion,
13
14 59 acknowledging that our results demonstrate that the height of the typical young aspen has
15
16
17 60 increased “more slowly than the tallest” young aspen. Instead, Painter *et al.* describe the utility of
18
19 61 5T sampling for detecting the *occurrence* of a wolf-elk-aspen trophic cascade. They emphasize
20
21 62 that “[t]he 5T method efficiently detected increases in heights of young aspen in stands that
22
23 63 historically had been suppressed by elk browsing.” While we agree that 5T sampling allowed
24
25
26 64 Ripple & Beschta (2007) to document “the first significant growth of young aspen in over half
27
28 65 century,” the occurrence of a height increase says little about the strength of the wolf-elk-aspen
29
30
31 66 trophic cascade, which was the central focus of Brice *et al.* (2022).

32
33 67
34
35 68 Painter *et al.* conflate the use of the 5T method for detecting trophic cascade *occurrence*
36
37 69 (changes in browsing and height of young aspen) with measuring trophic cascade *strength* (rate
38
39 70 of those changes across the aspen population). Painter *et al.* focus on previous work that used the
40
41
42 71 5T method to detect change, whereas we focused on previous work that used the 5T method to
43
44 72 describe the rate of change (Brice *et al.* 2022: Table 1). Our results suggest that these published
45
46
47 73 trends overestimate trends in the aspen population at large, affirming Ripple & Beschta’s (2007)
48
49 74 early acknowledgement that the 5T method does not provide a representative estimate of the
50
51 75 aspen population response. Therefore, Painter *et al.*’s statement that “the results of Brice *et al.*
52
53 76 actually supported the previous work they characterized as ‘biased’ and ‘exaggerated’” is not an

1
2
3 77 accurate description of our results or their implications. We emphasize that our study
4
5 78 characterized the 5T method as biased because it exaggerated estimates of population-level
6
7 79 changes in browsing and height of young aspen compared to random sampling.
8
9

10 80
11
12 81 Painter et al. also rely on the traditional assumption that a negative correlation between browsing
13
14 82 and height of young aspen is an exclusive indicator of browsing suppressing height of young
15
16 83 aspen. We found that height of young aspen is both a cause and an effect of reduced browsing. It
17
18 84 is a cause of reduced browsing because elk consume aspen at a 'preferred browsing height'
19
20 85 beyond which browsing pressure decreases as height increases (Brice et al. 2022: Figure 4a).
21
22 86 Thus, a negative correlation between browsing and young aspen height is not reliable evidence
23
24 87 of a wolf-elk-aspen trophic cascade because it does not represent an unambiguous causal link
25
26 88 between reduced browsing and increased height of young aspen.
27
28
29
30

31 89
32
33 90 Furthermore, Painter et al.'s argument that leader length (an index of growth rate and site
34
35 91 productivity) does not contribute to variation in height of young aspen is contradicted by their
36
37 92 data (Painter *et al.* 2015: Appendix A, Table A1) and our own (Figure 1). Together, these data
38
39 93 support the hypothesis that site productivity has an ecologically meaningful influence on young
40
41 94 aspen height in the northern Yellowstone study area.
42
43
44

45 95
46
47 96 In summary, we agree with Painter et al. that 5T sampling can efficiently detect the occurrence
48
49 97 of recruitment. However, understanding the full scope and outcome of the wolf-elk-aspen trophic
50
51 98 cascade requires more than knowing that it occurs. Knowledge about the strength of the cascade
52
53
54
55
56
57
58
59
60

1
2
3 99 is also vital, and this requires a random sampling design that provides a representative estimate
4
5 100 of the aspen population response to wolf-caused reductions in elk browsing pressure.

1
2
3 114 **Figure 1.** Effect of leader length (an index of growth rate and site productivity) on height of
4
5 115 randomly sampled, unbrowsed young aspen in northern Yellowstone National Park, 2007-2017
6
7 116 ($\beta = 0.013$, $SE = 0.0003$, $p < 0.001$). Results are population-averaged fitted values and associated
8
9 117 95% confidence intervals from a generalized linear mixed model (GLMM) of height of
10
11 118 unbrowsed young aspen ($N = 5,581$ leader stems, excluding 7 outliers with leader length > 100 -
12
13 119 cm) as a function of leader length with crossed random intercepts for stand identity ($N = 113$
14
15 120 stands) and year to account for (i) correlation between measurements taken on the same stand in
16
17 121 multiple years and on multiple stands in the same year, and (ii) unmeasured stand- and year-
18
19 122 related effects. Leader length equals the current annual growth of the leader stem. We treated the
20
21 123 leader stem as the unit of analysis and used a GLMM with a gamma distribution and a log link to
22
23 124 analyze total height of the leader stem, which took only non-negative values that were strongly
24
25 125 right skewed. The sample of young aspen included in this analysis is a subset of the sample
26
27 126 analyzed in Brice et al. (2022). The rug on the x-axis illustrates the distribution of the data.
