Natural fibers have drawn attention of researchers as an environmentally-friendly alternative to synthetic fibers. Developing natural fiber reinforced bio-composites are a viable alternative to the problems of non-degrading and energy consuming synthetic composites. This study focuses on (i) the application of kenaf fiber as a potential reinforcement and, (ii) determining the tensile properties of the randomly oriented short kenaf fiber composite both experimentally and numerically. Kenaf fiber micro-structure and its Young’s modulus with varying gage length (10, 15, 20, and 25.4 mm) were investigated. The variation in tensile strength of kenaf fibers was analyzed using the Weibull probability distribution function. It was observed that the Young’s modulus of kenaf fiber increased with increase in gage length. Fabrication of randomly oriented short kenaf fiber using vacuum bagging techniques and hand-lay-up techniques were discussed and the tensile properties of the specimens were obtained experimentally. The tensile modulus of the composite sample at 22% fiber volume fraction was found to be 6.48 GPa and tensile strength varied from 20 to 38 MPa. Numerical models based on the micro mechanics concepts in conjunction with finite element methods were developed for predicting the composite properties. A two-step homogenization procedure was developed to evaluate the elastic constants at the cell wall level and the
meso-scale level respectively. Von-Mises Fisher probability distribution function was applied to model the random orientation distribution of fibers and obtain equivalent modulus of composite. The predicted equivalent modulus through numerical homogenization was in good agreement with the experimental results.

Natural fibers have drawn attention of researchers as an environmentally-friendly alternative to synthetic fibers. Developing natural fiber reinforced bio-composites are a viable alternative to the problems of non-degrading and energy consuming synthetic composites. This study focuses on (i) the application of kenaf fiber as a potential replacement for glass fibers and (ii) determining the mechanical properties of the randomly oriented short kenaf fiber composite both experimentally and numerically. Kenaf fiber micro-structure and its mechanical properties with varying gage length (10, 15, 20, and 25.4 mm) were investigated. The variation in tensile strength of kenaf fibers was analyzed using a statistical method called Weibull probability distribution function. It was observed that the Young’s modulus of kenaf fiber increased with increase in gage length. Fabrication of randomly oriented short kenaf fiber using vacuum bagging techniques and hand-layup techniques were discussed and the tensile properties of the specimens were obtained experimentally. The tensile modulus of the composite sample at 22% fiber volume fraction was found to be 6.48 GPa and the tensile strength varied from 20 to 38 MPa. Simultaneously, a computer program (finite element method) was written to predict the tensile properties of composites.
using a micro mechanics approach. The predicted equivalent modulus through a computer program (finite element method) was in good agreement with the experimental results.
To my parents Laxmi and Balaiah, and all my teachers.
Acknowledgments

I would like to express my sincere gratitude to my advisor Dr. Thomas H. Fronk for the continuous support of my research work, for his patience, motivation, enthusiasm and immense knowledge. His supervision helped me in all the time of research and writing of this dissertation. I could not have imagined having a better advisor and mentor for my Ph.D. study.

Also, I would like to thank the rest of my dissertation committee: Dr. Barton L. Smith, Dr. Steven L. Folkman, Dr. Ling Liu and Dr. Paul Barr, for their encouragement and insightful comments. My appreciation also goes to the staff of the MAE department, Chris Spall, Karen Zobell and Terry Zollinger, who helped during the course of my study.

I thank my fellow lab mates Brian Spackman and Manjunath Prasad for all the support during experimentation. Also I thank my friends Naga Sai Ram Mallik, Abdulla Khan, Bhuvanesh Kumar, Arvind Konda and Varun for their continuous support and motivation during tough times.

Above all, I thank my parents Laxmi and Balaiah, my brother Jairam and my sister Jyothi for their love, support and understanding during the long years of my education.

Chapter 1
Introduction

1.1 Background

The composite material is processed from a mixture of two or more different materials in certain proportions. Generally speaking, composite comprises a fiber reinforcement embedded in a polymeric matrix. The motivation behind the invention of a composite material comes from the demand of low weight and high strength material for the aerospace industry. The major work in this area was carried out during 1960’s and to date there are several types of composites being developed for various applications [1]. Examples of some synthetic fibers are glass, carbon, boron, aramid and Kevlar. Commercially available polymer matrices include epoxy, polypropylene and polyethylene. Metals and ceramics are also used as matrix materials in composite processing. A wide range of these composite materials have been successfully used for structural applications in the aircraft, space, automotive, marine and infrastructure industries.

Generally, for structural applications, composite laminates are processed by stacking lamina with varying fiber orientations to achieve the desired structural behavior. Structural functionality includes high tensile load carrying members; low thermal expansion, thermal barriers etc; and sometimes discontinuous fiber composite as shown in Fig 1.1. The mechanical behavior of such laminates is anisotropic in nature, meaning it depends on the fiber and matrix properties, fiber orientation and volume fraction, the interface bond between fiber and matrix, and processing techniques. The choice of a particular composite processing technique depends on the type of matrix to be used for composite, either thermoset or thermoplastic. Techniques used for thermoset kind matrix include resin transfer molding, vacuum assisted resin transfer molding, compression resin transfer molding, and pultrusion process. Thermoplastic kind matrix includes compression molding, filament winding and
injection molding. Application of these techniques depends on the type of structure (flat or complex), rate of production and type of application.

![Layer Diagram](image)

**Fig. 1.1: Various Types of Composites**

Most of the existing composite materials (both fibers and polymers) are processed from petroleum based products and the previously mentioned processing techniques are power consuming. Consequently, some concerns associated with the commercially available composites are high energy consumption, non-recyclability, non-renewability and cost. There is a need for developing an alternate composite material or processing technique that is economical, low energy consuming and environmental friendly. In recent years, researchers explored the potential natural fibers (derived from plants and animals) as a replacement for synthetic fibers. An experimental investigation of some natural fibers conducted by S. V. Joshi et al.[2] proved to be capable of replacing E-glass fibers. At this point, before proceeding into details, the following questions must be answered:

- What is the morphology of natural fibers?
- Do these fibers have enough benefits to replace existing commercial fibers?
- How does one process a natural fiber reinforced composite?
- What are the major advantages and applications of natural fiber composites?
Natural fibers in this context imply those derived or obtained from plants. These fibers can be obtained from different parts of a plant, including the stem, leaf, root, core and fruit [3]. The fibers obtained from the stem are called bast fibers and those obtained from the leaf, root and fruit are called leaf fibers, root fibers and fruit fibers respectively. Examples of bast fibers are hemp, flax, kenaf, and jute, leaf fibers are abaca, sisal and pineapple, and fruit fibers are cotton, coir and kapok [3]. A summary of worldwide production of various natural fibers was given in [3, 4]. It was observed that the bast fibers are most commonly used, followed by leaf and fruit fibers, proving their abundance in nature. This is why past few years of research have focused on using bast fibers as a replacement for synthetic fibers. The potential of various bast fibers as a composite reinforcement is discussed in the subsequent sections. Once the source for fibers has been chosen, the next step is extracting fibers from the stem (known as retting). Various retting processes currently used in industry include dew-retting, water retting, chemical retting and physical methods [4]. The effect of retting methods on the bast fiber properties was collectively discussed in a review article [4]. Water retting results in good quality fiber but takes 2-3 weeks, whereas chemical retting is done quickly and results in decreased strength of the fibers. The process of retting is followed by decortication, carding and spinning into yarn. The full process of various fiber extractions [5] is shown in Fig 1.2.

The potential (specific modulus) of the natural fibers as a reinforcement was studied by Wambua et al. [6] and shown in Table 1.1. Five different fibers; sisal, kenaf, hemp, jute and coir were selected in [6] and a polypropylene matrix based composite was processed. The mechanical properties of these composites were compared to that of E-glass fiber reinforced composites. Specific modulus of natural fiber reinforced and E-glass fiber reinforced composites were reported to be comparable except in the case of coir. Earlier
research focused on flax, hemp, bamboo and jute fibers due to their abundant availability and extensive use in the textile industry. This study will focus on a similar common fiber source, the kenaf plant. Kenaf fiber secures third place in terms of worldwide production (870,103 ton per year) after jute. In addition to its availability, kenaf belongs to the same family as the jute plant [7] and is likely to share jute’s desirable properties. There is a need for research about kenaf fiber properties and its surface characteristics if it is to become a successful reinforcement for composite production.

Unlike artificial fibers, natural fibers show great variation in their mechanical properties due to: growth conditions, age of the plant, which part of the stem they are extracted from, varying constituent’s fraction at the microscopic level, etc. Shinji Ochi [8] reported the variation of kenaf fiber modulus as a function of fiber location on the stem, where fibers obtained from the bottom part of a plant exhibited more tensile strength (about

![Diagram of processing steps of natural fibers](image)
20% more). The tensile strength of a fiber determined experimentally at the macroscopic scale is governed by the structure and the chemical composition present at the microscopic scale. Most of the materials available in nature are composite in nature (i.e. the material is a mixture of different chemical constituents). Similarly, bast fibers also consist of constituents namely: cellulose, hemicellulose, lignin, pectin and waxes at the microscopic scale [3]. Fibers obtained from different plants have variation of these constituents and consequently exhibit different properties. The volume fraction of each constituent in different fibers was reported in [3, 4] and is presented here in Table 1.2.

The major advantages of developing natural fiber based composites include low cost, low density, recyclability, low pollution, no health hazards and effective utilization of resources [2]. To this point, natural fiber composites can be used for secondary structural application due to their lower tensile strength and mechanical properties compared to that of primary structural applications. Some applications were listed in [10, 11] that includes seat backs, dashboards, door panels, and sports goods. In order to expand the use of natural fiber based composites, further detailed investigations are required with a focus on strength improvement.

1.2  Kenaf Fiber as Reinforcement for Composites

Kenaf (Hibiscus Cannabinus) is an annual herbaceous fiber plant from the tropical and subtropical regions of Africa and Asia [12, 13]. It is also found in the parts of Europe and USA. Kenaf plants grow up to 4m in about 3-4 months with a base diameter of 3-5 cm. The cost of kenaf fibers in the year 2000 was $278-302 per ton and 15MJ of energy was consumed to produce 1 kg of kenaf fiber, where glass fibers consumed 54MJ [14]. After processing, the average length of a kenaf fiber available in the market is around 70 mm with the diameter ranging from 10 μm to 80 μm. The potential of kenaf fiber as a reinforcement in composite was reported by various authors [6, 12, 15] in the past by comparing the specific modulus of a composite with that of glass fiber reinforced composite. The tensile modulus of kenaf fiber reinforced polypropylene composite was reported to be the same as that of glass fiber mat reinforced composite [6] at 22% volume fraction. A discussion on
manufacturing problems of kenaf fiber reinforced composite, due to the limited available length of fiber, was produced by Zampaloni et al. [12]. They concluded that the short fiber and compression molding technique resulted in a composite with 40% weight fraction of fiber and greater specific strength compared to E-glass fiber composite. Most of the research investigations in the past were conducted on composites processed through thermoplastic techniques that required high temperature and pressure during processing. These higher temperatures (160°C), resulted in reduced tensile strength [8] which consequently resulted in reduced composite properties. An alternative to thermoplastic processing is thermoset processing, which does not require higher temperatures. It is also a good technique for fabrication of complex structures.

The Young’s modulus of kenaf fiber varied from source to source [7]. Many factors, such as growth conditions, location on the stem from where the fiber is obtained, varying composition of basic constituents, and defects such as kink bands, can influence the fiber properties. Along with the above mentioned factors, the cross sectional area calculation of the fiber also plays a vital role in determining the Young’s modulus. The effective properties of a composite are a function of fiber volume fraction, Young’s modulus and its geometry, orientation of fibers, interfacial bonding between fibers and matrix and defects such as voids. Therefore, the behavior of kenaf fibers should be explored in detail. To the authors knowledge, neither has there been significant effort to determine the interfacial properties of kenaf fiber and epoxy matrix, nor to explore the option of short kenaf fiber as reinforcement.
This study aims at determining Young’s modulus of kenaf fiber and its composite (fabricated through hand-lay-up technique) and develop a numerical homogenization model to predict the effective properties of the composite. Objectives are discussed more specifically in the next chapter.

1.3 Review of Literature

The organization of this section is as follows: micro-structure of bast fiber, mechanical properties of kenaf fibers and its composites.

Micro-structure of any bast fiber consists of a bundle of cell walls together with a middle lamella as an interfacing layer. Cell walls are hollow laminated composite tubes (cross-section) consisting of Primary (P) and Secondary (S1, S2 and S3) layers with varying micro fibril or cellulose orientation in each layer. Volume fraction of basic constituents in kenaf fiber is: cellulose 44% - 72%, hemicellulose 20%-22% and lignin 9%-19% based on values presented in Table 1.2. The schematic representation of cell wall structure of a bast fiber is shown in Figure 1.3. The micro-structure of a kenaf fiber obtained from an optical microscope and a scanning electron microscope is presented in Chapter 3.

![Fig. 1.3: Schematic Representation of Bundle of Cell Walls in Bast Fiber](image)

It is a well-known fact that the effective properties of a composite are governed by the

properties of a fiber, matrix and fiber/matrix interface. Experiments were conducted to calculate kenaf fiber modulus, considering fixed gauge length, loading rate, and the effect of moisture content. The results were collectively reported in several review papers, which are compiled and presented in Table 1.3. A significant variation in tensile strength and modulus values were observed due to varying chemical composition in fibers and uncertainties associated with measurements of fiber dimensions. Measuring a cross-sectional area of a fiber provides a major challenge, which is significant in calculating stress and determining the Young’s modulus of a kenaf fiber. Any assumption of a circular, elliptical or other cross-sectional shape will produce results with more uncertainty. Obtaining specimen dimensions (gage length) of the fiber to be tested is vital in calculating a reliable Young’s modulus. Studies conducted on the sisal fibers [18] showed that there is no effect of gage length on the fiber properties, whereas studies conducted on polymeric fibers [19] showed that gage length plays a major role, with defects increasing with an increase in length. There has been no significant effort made to obtain reliable value of kenaf fiber modulus by considering the rate of loading, standard gage length and appropriate techniques for cross-sectional area.
measurement.

Kenaf fibers were mostly reinforced in a PLA/PP polymeric matrix and tensile (Table 1.4), flexural and impact properties were obtained. Tensile modulus of these kinds of composites were already discussed in section 1.2. Not many studies have been conducted on using thermoset polymers, though they provide more wettability, lower cost and are more effective for manufacturing of complex shapes. To attain composites with increased strength, effects of kenaf fiber surface treatments were investigated. 3% maleated anhydride poly-propylene (MAPP) improved the strength by 30% [19] and 3% alkali improved the strength by 20% [20].

Most of these results were based on an indirect measurement technique (i.e., composites were fabricated from chemically treated fibers and the strength of the composite was measured). This method does not guarantee the optimum volume fraction of fibers, as the fiber aspect ratio is not known. A single fiber pull out test will result in evaluating fiber/matrix interfacial strength and fiber aspect ratio, which governs the composite properties. Detailed interfacial studies [21] were conducted on flax and hemp fibers that showed that 9 mm and 13 mm are the critical lengths for complete stress transfer.

Little attention has been given to numerical modeling of the composites reinforced with natural fibers. Few models were developed in the past for modeling the behavior of wood and fibers using laminate theory. These are discussed in Chapter 4 in detail. From the literature, it can be concluded that there is a need for fundamental investigations on obtaining appropriate tensile modulus of a kenaf fiber, elastic constants of kenaf fiber reinforced epoxy composite and numerical modeling a natural fiber composite. Dissertation
objectives were set based on the conclusions from existing literature and are presented in the next chapter.

1.4 Structure of Dissertation

This dissertation is divided into five chapters followed by references at the end. The chapters are as follows:

1. Introduction

2. Research Objectives

3. Experimentation

4. Numerical Modeling

5. Summary, Conclusion, and Future Work

The first chapter discussion involves the background of natural fiber composite, a literature review and some conclusions drawn from the past research, based on which the dissertation work was established. Chapter 2 lists the research objectives followed by a section explaining the approach used to accomplish the objectives. Chapter 3 explains the experimental work carried out to determine tensile modulus of kenaf fibers, fabrication technique of kenaf fiber reinforced composite, and concludes with an evaluation of Young’s modulus and Poisson’s ratio through tensile tests. Chapter 4 provides the 3D finite element micromechanical model of natural fiber composite to predict the homogenized or effective properties of natural fiber composite. Chapter 5 summarizes the research study, findings and conclusions from this work, and proposes further future work.
Chapter 2
Research Objectives

2.1 Objectives

• To determine the Young’s modulus of a kenaf fiber through tensile test by considering the appropriate fiber cross-sectional area after failure.

• To determine Young’s modulus and Poisson’s ratio of a kenaf short fiber reinforced composite.

• To develop a RVE based model of a randomly oriented kenaf short fiber composite that predicts the approximate effective properties of a composite as a function of fiber volume fraction and its equivalent properties.

2.2 Research Approach

Based on the research objectives established in the previous section, the following tasks have been identified and proposed. The tasks can be divided into two main categories: experimentation and numerical modeling.

Experimentation

• To explore the micro-structure of kenaf fiber bundles through optical microscopy and scanning electron microscope examination. This task will help in understanding the structural morphology of the fiber.

• To find out a novel technique for evaluating the cross-section of kenaf fiber during a tensile test. This plays a major role in evaluating the tensile modulus of kenaf fiber.

• To investigate the effect of gage length on Young’s modulus of kenaf fiber subjected to quasi-static loading. The purpose of this task is to examine the strength-limiting
defect over a certain length of fiber. With the increase in gage length, there is a possibility of included defect that limits the tensile strength of the fiber.

- To fabricate the kenaf short fiber epoxy composite by vacuum bagging technique and hand-lay-up technique. This task involves two processing techniques in preparing the tensile test specimens.

- To perform a tensile test on kenaf fiber reinforced composites and evaluate the Young’s modulus and Poisson’s ratio.

Numerical Modeling

- To predict the elastic constants of cell wall layers in bast fiber through unit cell modeling of the structure at the microscale. The elastic constants as a function of varying volume fractions of basic constituents in each layer of cell wall will be studied by developing a parametric 3D finite element model.

- To predict the effective properties of a unidirectional natural fiber composite through unit cell modeling of the structure at the meso-scale. This homogenization model incorporates the elastic constants obtained from the previous step as the cell wall layer properties. Also, the effective properties as a function of micro fibril angle in the S2 layer of cell wall will be investigated.

- To generate the RVE geometry of randomly oriented short fibers by applying the Von-Mises Fisher probability distribution function.

- As a final step, applying the orientational averaging technique (Von-Mises Fischer PDF) on the unidirectional composite properties to evaluate the quasi-isotropic properties of a randomly oriented short fiber composite.
Chapter 3

Experimentation

3.1 Micro-Structure of Kenaf Fiber

The micro-structure of a natural fiber consists of a cell wall bundle, as stated in Chapter 1. The shape of a cell wall is polygonal and governs the cross-sectional geometry of a fiber. This section presents the micro-structure of kenaf fibers examined under an optical microscope and scanning electron microscope (SEM). To view the micro-structure under an optical microscope, a polished mounting specimen was prepared with kenaf fibers encased in an epoxy matrix. The cross-section of kenaf fibers obtained at 50X magnification are shown in Figure 3.1. Figure 3.1(a)-3.1(d) reveals the inconsistency in cross-sectional shape and the presence of voids called lumen in the cell wall. The cell walls are seen to be circular or elliptical in the optical microscopic images. A scanning electron microscope (SEM) image of a single kenaf fiber, as shown in Figure 3.2, depicts the delamination of cell walls and kink bands. A single cell wall image shown in Figure 3.2(b) is hollow and rectangular in shape, with dimensions $13 \mu m \times 7 \mu m \times 2 \mu m$.

The optical microscopic images obtained along the axial direction of kenaf fibers (as shown in Figure 3.3) displays the defects present in the fiber. The possible defects along the fiber axial direction include varying diameter, fiber damage and delaminated cell walls. These defects combined with fiber anisotropy at micro scale level play an important role in the fiber properties.

3.2 Influence of Gage Length on Kenaf Fiber’s Young’s Modulus

The tensile modulus of artificial fibers (glass, carbon, Kevlar) and natural fibers depends on the test speed and their gage length [23]. When compared with artificial fibers, kenaf fibers display more uncertainty towards the consistent properties. The tensile testing
3.2.1 Materials and Procedure

The carded kenaf fibers, averaging 70mm in length, were obtained from Bast Fiber LLC. The gage lengths of 10, 15, 20 and, 25.4 mm were chosen to study the influence of gage length on fiber properties. At least ten specimens were tested for each gage length as

A paperboard of width (25.4mm) suitable for tensile testing was prepared with varying gage lengths as shown in Figure 3.4(a). The fibers were fixed on the paperboard as per ASTM D3822 standards and shown in Figure 3.4(b). A tensile test was performed on the Instron 5848 micro tensile tester machine maintaining an extension rate of 1 mm/min [24]. Before testing each individual fiber, auto calibration was done and load-extension curve was recorded. The detailed procedure is explained below:
Procedure

1. A single kenaf fiber (technical fiber) of length 60-70mm was randomly selected from the sample (up to 15 fibers).

2. As the fibers are naturally curved, they were straightened with proper care while being fixed on the paperboard. The fiber fixation on paperboard is shown in Figure 3.4(b).

3. Using forceps, the prepared paper frame in step 2 was carefully mounted on the tensile testing machine and the grips were tightened, followed by cutting the paper frame as shown in Figure 3.4(c).

4. Bluehill software available on the Instron machine was launched and auto calibration was done. Tensile testing speed was set to 1 mm/min to carry out a quasi-static test and the load-extension curve of fibers was recorded.

5. Specimens that failed close to grip or slipped during the test were discarded and the data of at least 10 specimens were recorded.

6. The tested fibers were carefully stapled to the paper, which was later used for evaluating the cross-sectional area of fibers at the break point.

3.2.2 Cross-Sectional Area Measurement

The cross-sectional image of kenaf fiber was acquired using an optical microscope, based on the assumption that cross-section remains the same after failure. The mounted specimen, for observation under an optical microscope, was prepared by following the procedure described below:

Procedure

1. Two rectangular hollow boxes (top mold and bottom mold), as shown in Figure 3.5, were prepared using MPPA blocks.
2. Double sided tape (blue) was fixed on the faces of the bottom block to adhere to the fibers.

3. Fibers were carefully attached to the tape, so that the break point of the fiber was close to the edge of the block.

4. The upper mold was placed on the bottom block to create a full box and sealed on all sides using duct tape.

5. The mixed epoxy resin was poured into the mold and left for curing.

6. The resulting mounted sample from Step 5 was grinded and polished to prepare the specimen for observation under an optical microscope.

Four such mounted specimens were prepared, each corresponding to a particular gage length, and images were acquired at 50X magnification. The acquired images were then analyzed using an ImageJ software to evaluate the cross-sectional area. The process of measurement requires an image of the calibrated scale (stage micrometer), acquired at the
same magnification as that of the fiber. In this study, a Nikon stage micrometer with 0-1 mm range was used as a calibration scale, shown in Figure 3.6. The optical microscopic images and the evaluated images from ImageJ software are presented in Appendix Table A.1-A.4

![Fig. 3.6: Calibration Scale at 50X Magnification](image)

3.2.3 Uncertainty in Area Calculation

The linear dimension associated with the image was evaluated as a product of conversion factor \((k)\) and the number of pixels occupied by the image. Mathematically, it is expressed as \([25,26]\),

\[
 s = kN 
\]

where \(k\) is the conversion factor and \(N\) is the number of pixels.

Following Taylor Series Method (TSM) approach [27], the uncertainty associated with the
image based measurement is expressed as:

\[
\left( \frac{u_s}{s} \right)^2 = \left( \frac{u_k}{k} \right)^2 + \left( \frac{u_N}{N} \right)^2
\] (3.2)

where \( u_s, u_k \) and, \( u_N \) are the uncertainties associated with the linear dimension, conversion factor and the number of pixels respectively. The uncertainty associated with conversion factor \( k \) is given by Equation 3.3 [26]

\[
\left( \frac{u_k}{k} \right)^2 = \left( \frac{u_m}{m} \right)^2 + \left( \frac{u_{Nl}}{Nl} \right)^2
\] (3.3)

where \( m \) is the dimension on calibration scale and \( Nl \) is the number of pixels obtained for the calibrated length.

The uncertainty quantification of each term in Equation 3.3 was done by assuming probability distributions as presented in [26]

\[
u_{Nl} = \frac{1}{2\sqrt{12}}
\] (3.4)

\[
u_m = \frac{0.5 \times \text{Least dimension on calibrated scale}}{\sqrt{3}}
\] (3.5)

\[
u_N = \frac{1}{2\sqrt{6}}
\] (3.6)

The uncertainty of cross-sectional area is then quantified as

\[
\left( \frac{u_A}{A} \right)^2 = \left( \frac{u_N}{N} \right)^2 + 4 \times \left( \frac{u_k}{k} \right)^2
\] (3.7)

3.2.4 Uncertainty in Young’s Modulus

The tensile (initial) modulus of kenaf fiber was evaluated using the expression given in ASTM D638 Standard. The stress-strain curve of kenaf fibers obtained for various gage lengths are shown in Figure 3.7 and 3.7. Compliance correction was neglected during calculations, as the cross-sectional dimensions vary from fiber to fiber. Following the step by step procedure explained in [28], the uncertainty associated with the tensile modulus
was quantified.

The slope and standard deviation associated with the load-deformation curve of a fiber was calculated using Equations 3.8 and 3.10,

\[ m = \frac{n \sum_{i=1}^{n} x_i y_i - \left( \sum_{i=1}^{n} x_i \right) \left( \sum_{i=1}^{n} y_i \right)}{\sqrt{\sum_{i=1}^{n} x_i^2 - \left( \sum_{i=1}^{n} x_i \right)^2}} \]  

\[ b = \frac{\sum_{i=1}^{n} y_i - m \sum_{i=1}^{n} x_i}{n} \]  

\[ S_m = \sqrt{\frac{1 - r^2}{n(n-2)}} \frac{S_y^2}{S_x^2} \]  

where

\[ S_{xy} = \frac{1}{n-1} \left[ \sum_{i=1}^{n} x y_i - \frac{\sum_{i=1}^{n} x_i \sum_{i=1}^{n} y_i}{n} \right] \]  

\[ S_x = \sqrt{\frac{1}{n-1} \left[ \sum_{i=1}^{n} x^2 - \left( \frac{\sum_{i=1}^{n} x_i}{n} \right)^2 \right]} \]  

\[ S_y = \sqrt{\frac{1}{n-1} \left[ \sum_{i=1}^{n} y_i^2 - \left( \frac{\sum_{i=1}^{n} y_i}{n} \right)^2 \right]} \]  

\[ r = \frac{S_{xy}}{S_x S_y} \]  

The Young’s modulus of a fiber in terms of stiffness is then expressed as Equation 3.15

\[ E = \frac{m L}{A} \]
and the uncertainty according to TSM approach is given by Equation 3.16. The Young’s modulus with associated uncertainty is shown in Figure 3.8

\[
\left( \frac{u_E}{E} \right)^2 = \left( \frac{u_m}{m} \right)^2 + \left( \frac{u_L}{L} \right)^2 + \left( \frac{u_A}{A} \right)^2
\]

Young’s Modulus 10.948 ± 1.694 GPa
Remarks on Young’s Modulus

1. The stress-strain curve of kenaf fiber exhibited linear behavior and brittle failure.

2. Based on the weakest links theory, the tensile strength of each fiber is influenced by the defects present along the length of the fiber and voids present in the cross sectional area. More detailed statistical analysis is presented in the next section.

3. The micro fibril orientation at the microscopic scale also plays a major role in the tensile properties of kenaf fiber.

4. The tensile modulus of kenaf fiber as a function of gage length was observed from the experiment. Though the wide variability in Young’s modulus was seen in the data presented in Table 3.5-3.8, an overall observation suggests that the Young’s modulus decreased with a decrease in gage length. The mean values of Young’s modulus
calculated are 10.948, 18.845, 23.23 and 30.994GPa for gage lengths of 10, 15, 20, and 25.4 mm respectively.

3.2.5 Weibull Analysis for Tensile Strength of Kenaf Fiber

Kenaf fiber exhibited the brittle failure mode under tensile loading, and it was observed that the tensile strength varied among fibers. Such brittle behavior of the fiber is governed by the number of flaws present in the volume of material [29]. Strength characterization of brittle materials is mathematically expressed by a probability distribution function known as Weibull Distribution. This mathematical expression used to explain the probability of failure of a chain with \( n \) weakest links, is given as [30]

\[
\phi(z) = 1 - \exp \left( \left( \frac{z - z_o}{z_s} \right) ^ \beta \right)
\]

where \( z_s \) and \( \beta \) are scale and shape parameters respectively. Weibull distribution (CDF)

Fig. 3.9: Weibull Probability Density Function with Varying Shape and Scale Parameters

[31] applied for strength characterization of brittle materials, based on the assumption that
the strength of a material is directly proportional to volume of flaws $V$, yields

$$P(\sigma) = 1 - \exp \left[ -V \left( \frac{\sigma}{\sigma_o} \right)^m \right]$$  \hspace{1cm} (3.18)

where $P(\sigma)$ is the probability of fiber failure below specified stress $\sigma$, $V$ is the volume of flaws, $m$ is the Weibull modulus and $\sigma_o$ is the characteristic strength. The higher value of the Weibull modulus $m$ signifies less variation in the tensile strength of a material.

When the cross-sectional area is constant, Equation 3.18 can be modified and expressed as Equation 3.19. The average strength of the material is then evaluated as the expectation of distribution as shown in Equation 3.20.

$$P(\sigma) = 1 - \exp \left[ -L \left( \frac{\sigma}{\sigma_o} \right)^m \right]$$  \hspace{1cm} (3.19)

$$\bar{\sigma} = \sigma_o \Gamma \left( 1 + \frac{1}{m} \right) L^{-\frac{1}{m}}$$  \hspace{1cm} (3.20)

Application of the equation 3.19 was observed to be inadequate in characterizing the strength of Nicalon ceramic fibers with varying diameters [32]. Therefore, a three parameter model was proposed by Zhu et al. [31, 32], as shown in Equation 3.21, which takes diameter of fiber into account. The three parameters $m, h, \sigma_o$ were determined from experimental data.

$$P(\sigma) = 1 - \exp \left[ -L d^h \left( \frac{\sigma}{\sigma_o} \right)^m \right]$$  \hspace{1cm} (3.21)

$$\bar{\sigma} = \sigma_o \Gamma \left( 1 + \frac{1}{m} \right) L^{-\frac{1}{m}} d^{-h}$$  \hspace{1cm} (3.22)

In recent years, significant efforts have been made by researchers to develop the statistical model for strength characterization of natural fiber [33-37]. A Modified Weibull model was proposed by Xia et al. [38], as given in Equation 3.23, where $\gamma$ accounts for diameter variation within the fiber. This model predicted the average strength of fiber more accurately than the two and three parameter model. In his study, Anderson [37] applied the Weibull of Weibull (WoW) model to characterize the strength of flax fibers. Weibull
of Weibull (WoW) model was developed by Curtin [39], which accounted for incorporating the characteristic strength itself as a Weibull distribution.

\[
P(\sigma) = 1 - \exp \left[ -L^\gamma \left( \frac{\sigma}{\sigma_o} \right)^m \right]
\]

(3.23)

\[
\bar{\sigma}^2 = \bar{\sigma}^2_1 \left( \frac{L_2}{L_1} \right)^{\frac{2}{m}}
\]

(3.24)

In this section, the procedure for evaluating the parameters associated with each Weibull model is explained. The computed values are presented in Table 3.5-3.7. The cumulative distribution function, corresponding to each model, was plotted against the experimental data to observe the parameter fit.

**Steps for Two Parameter Model**

(a)

1. The tensile strength of all the fibers were arranged in ascending order. The \( P(\sigma) \) value corresponding to each tensile strength was estimated as \( i \) \( \frac{N}{N+1} \), where \( i = 1, 2, 3, \ldots, N \) specimens.

2. The plot of \( \ln(-\ln(1 - P(\sigma))) - \ln(V) \) vs \( \ln(\sigma) \) was obtained for the tensile strength data, and Weibull modulus \( m \), characteristic strength \( \sigma_o \) was estimated for the slope and intercept of the curve respectively as shown in Figure 3.10.

(b)

\[
P(\sigma) = 1 - \exp \left[ -d^h \left( \frac{\sigma}{\sigma_o} \right)^m \right]
\]

(3.25)

1. Assumption of constant gage length results in Equation 3.25, which implies probability of failure is function of diameter.

2. The value of \( \frac{h}{m} \) was obtained by plotting \( \ln(\sigma) \) vs \( \ln(d) \) and computing the slope.

3. A trial \( h \) value was assumed, and a \( \ln(-\ln(1 - P(\sigma))) - h \ln(d) \) vs \( \ln(\sigma) \) plot resulted in a \( m \) value, which is the slope of a line. An update \( h \) value is evaluated as \( m \) times the value obtained in Step 2. This process is continued till the \( h \) value converges.
4. The parameters \( h, m, \sigma_o \) were obtained for each gage length by following Steps 2 and 3 and the corresponding plots of probability distribution are shown in Figure 3.11. Cumulative distribution plots from the evaluated parameters are shown in Appendix Figure B.1

Fig. 3.11: Linear Fit for Two Parameter Weibull Model with Diameter Dependence (Contd)
Steps for Three Parameter Model

Based on the average strength, \( \bar{\sigma} = CL^\alpha D^{-\beta} \), taking a logarithm on both sides

\[
\ln \bar{\sigma} - \alpha \ln L = \ln C - \beta \ln D
\]  
(3.26)

\[
\ln \bar{\sigma} + \beta \ln D = \ln C + \alpha \ln L
\]  
(3.27)

1. An assumed value of \( \alpha \) is substituted in Equation 3.26 and \( \beta \) is obtained from the plot of \( \ln \bar{\sigma} - \alpha \ln L \) vs \( \ln D \).

2. The obtained value of \( \beta \) is substituted in Equation 3.27 to obtain new \( \alpha \). This iteration is carried out until \( \alpha \) and \( \beta \) converge. The cumulative distribution plot for all the data put together is shown in Figure 3.12. The cumulative distribution plot for consistent data is shown in Appendix Figure B.2

Steps for Weibull of Weibull Model

1. The plots of $\ln(-\ln(1 - P(\sigma)) - \ln(V)) vs \ln(\sigma)$ were obtained for each gage length and Weibull modulus $m$, characteristic strengths $\sigma_o$ were estimated as the slope and intercept of the line respectively.

2. The plots of $\ln (-\ln (1-P)) vs \ln (\sigma_o)$ were obtained for each gage length and the parameter $\xi$ and $\chi$ were estimated as the slope and intercept of the curve respectively.

3. The parameters $\gamma$, $\alpha$ and $\Sigma$ were evaluated for a batch of fibers using Equations 3.28 - 3.30 given by Curtin.

$$\alpha = \frac{\xi}{\sqrt{\xi^2 + m^2}} \quad (3.28)$$

$$\rho = \frac{\xi m}{\sqrt{\xi^2 + m^2}} \quad (3.29)$$

$$\Sigma = \left[ 1 - (m^2 + \xi^2)^{-0.75} \right] \chi \quad (3.30)$$

Fig. 3.13: Cumulative Distribution Function of Three Parameter Model for Consistent Data (Contd)
3.2.6 Results and Discussion

1. The fundamental assumption of the Weibull model, that the flaws are directly proportional to the length, was observed to be inverse in this case. The tensile strength was observed to decrease with increasing volume.

2. The Weibull model with diameter dependence corresponds well with individual fiber lengths as observed in Figure B.1

3. Parameters determined for the three parameter Weibull model, given by Equation 3.26 for full tensile strength data of fiber batch, fits well with 10, 15, 20 mm gage lengths, as shown in Figure 3.12.

4. Tensile strength of fibers with consistent Young’s modulus was selected and a three parameter model was fit as shown in Figure B.2. The difference in the fit is due to the varying diameter from fiber to fiber.
5. Parameters for Weibull of Weibull model (WoW), was observed to fit with the tensile strength data of 25.4 and 20mm gage length, whereas for 15 and 10 mm there was a wide range of discrepancy. This suggests that there is less scatter in data for 10 and 15 mm fibers compared to that of 25.4 and 20mm.

6. Average tensile strength predicted from WoW models are very similar to the experimental data as observed in Figure 3.14

3.3 Tensile Modulus of Kenaf Fiber Composite

In this section, the preparation of a tensile specimen and evaluation of tensile modulus is discussed. The tensile modulus and Poisson’s ratio of epoxy matrix was evaluated through tensile tests and a similar procedure was carried out on a kenaf composite specimen.

3.3.1 Specimen Preparation

![Mold for Casting Tensile Specimens](image)

Fig. 3.15: Mold for Casting Tensile Specimens
**Epoxy**

The epoxy resin PT2050 and hardener B1 were obtained from PTMW industries. Their density is 0.9 g/cc. The resin and hardener were mixed in 100:27 proportion according to the manufacturer’s specification. A mold, as shown in Figure 3.15, was designed for casting 10 tensile specimens at a time and, the dimensions of the specimen were selected from ASTM D638 type I. Mixed epoxy was pour into mold and left for curing in oven at 80°C for 12 hrs. Meniscus formed on top of the epoxy matrix sample was ground using 320, 600, 1200 grit sand paper, until the specimen was flat. The epoxy samples before and after grinding is shown in Figure 3.16.

![Epoxy Samples](image)

**Kenaf Composite**

The kenaf fibers were chopped to a length of 10-15 mm and soaked in a 3% Na OH solution for 12 hrs to remove any impurities present on the surface of the fiber. The Na OH solution was then drained and the fibers were oven dried at 80°C for 8 hrs. The dried kenaf fibers were shredded using carding brushes and mixed with an epoxy matrix such that a 22% fiber volume fraction was maintained. The mixture was then placed in mold as shown in Fig 3.17. Pressure was applied to the composite mix by tightening the clamps and left for curing at 80°C for 12 hrs. An attempt was made to cast the composite through vacuum bagging as shown in Fig 3.18. This process proved problematic, as there was no way of ensuring a flat top surface in the end product.
3.3.2 Experimental Setup

The experimental setup for tensile tests included load cell, strain gage and Vernier calipers as measuring devices to measure force, strain and specimen dimensions respectively.
Tests were performed on the Tinius Olsen tensile tester (Figure 3.19(a)) available in the material science lab at USU. In general, when tensile tests are performed on this machine force and extension readings are obtained through the Navigation software provided by the manufacturer. In this study, a data acquisition system was designed to acquire force and strain readings (axial and transverse) through a NI 9237 module, as shown in Figure 3.19(c). The NI 9237 module reads the Wheatstone bridge output in terms of voltage and converts to the desired unit such as force and strain.

(a) Tinius Olsen Testing Machine Frame  (b) Load Cell on Machine Frame  
(c) DAQ setup

Fig. 3.19: Tensile Test Setup

3.3.3 Load Cell and Calibration

The load cell, shown in Figure 3.19(b) attached to the testing machine is an S-shaped bending load cell constructed on the principle of a Wheatstone full bridge. The output terminal of the load cell is a 15 pin D-sub connector, with only four pins associated with the bridge terminals. The connection details are shown in Figure 3.20. A calibration curve
was generated using a bridge (mV/V) module of NI 9237 as explained below. The load cell was built based on the Wheatstone bridge principle. The output is read in millivolts. The change in the voltage of the bridge is proportional to the load applied. A calibration curve was generated for the load cell using the output (millivolts) of bridge for corresponding calibrated loads applied as shown in Figure 3.21(c). This procedure involved obtaining voltage readings for both loading and unloading of calibrated loads (Figure 3.21(d)) using LabVIEW generated code Figure 3.21(a)-3.21(b). A least squares linear regression method was applied to the calibration data and the resulting voltage-force conversion equation was obtained as shown in Figure 3.22. This equation was needed as input for NIDAQ9237 to convert the bridge output (millivolts) to Newton while performing tensile tests.

Fig. 3.20: Load Cell Wiring Diagram
Fig. 3.21: Load Cell Calibration
3.3.4 Tensile Testing

The epoxy samples and kenaf composite samples were prepared as explained in the previous section and strain gages were fixed on the sample as shown in Figure 3.23. The LabVIEW code is presented in Appendix Figure B.3. The sample was aligned in the loading direction and the grips were fixed tightly enough to prevent slipping. The testing speed was set to 8 mm/min as per ASTM standards and the tensile test was performed until the specimen failed. The specimens that failed during the test are shown in Figure 3.23 and Figure 3.24. The Young’s modulus and Poisson’s ratio was calculated using the procedure explained in [28] and presented in Table 3.8. A similar procedure was followed for determining kenaf fiber composite properties and the properties of the material were presented in Table 3.10.

Young’s Modulus $\pm 0.572$ GPa

3.3.5 Results and Discussion

![Stress-Strain Curve of Kenaf Fiber Composite](image)

Fig. 3.25: Stress-Strain Diagram Kenaf Fiber Composite
1. Kenaf fiber composite exhibited linear brittle failure with a tensile strength in the range of 20-38 MPa. These values are comparable to that of the tensile strength of other natural fiber composites published in [40, 41].

2. The Poisson’s ratio varied from specimen to specimen and in the range of 0.28 to 0.43. A possible reason might be the fiber orientation and inconsistent micro-structure at the point where the strains were measured.

3. The Young’s modulus of the composite was observed to be 6.48 pm 0.572 GPa for 22% volume fraction of kenaf fibers and comparable to that of glass fiber composites, as published in [42].

4. The lower tensile strength of the composite was attributed to the amount of voids present in the specimen due to insufficient pressure applied while casting specimen.
Chapter 4
Numerical Modeling

4.1 Introduction

This chapter presents the numerical model of a kenaf short fiber reinforced composite in order to predict the effective properties. Finite element method was applied as a computational tool to accomplish this objective. To predict the effective properties of a unidirectional kenaf fiber composite, a two-step numerical homogenization was carried out on a unit cell at the micro- and meso-scales. The following sections of this chapter explain the finite element formulation for the homogenization of a unit cell, Von-Mises Fisher probability distribution and the orientational averaging technique to determine the effective properties of the short fiber composite.

The unit cell is defined as the smallest repetitive part of the structure, as shown in Figure 4.1. In the field of composites, it is a very common practice to assume that the fibers are periodically arranged as a reinforcement in a matrix at the micro-scale. This leads to two types of basic unit cell models, square and hexagonal, which have been studied by various researchers [43-46] in the past. The volume fraction of constituents in a unit cell is same as that of a composite. The motivation behind selecting the unit cell was to reduce the computational effort involved in analyzing the whole micro-structure. The appropriate boundary conditions [46] were applied to the unit cell and a stress-strain field was predicted, leading to evaluation of macroscopic (homogenized) properties. The influence of homogeneous and periodic boundary conditions on unit cell was described in [47, 48], which proved that the former is an over-constrained boundary condition.

Macroscopic stress (Σ) is defined as the volumetric average of a microscopic stress (σ_{ij}) field in a body subjected to a uniform macroscopic strain (E). The macroscopic properties of a material can be derived from the analysis of microscopic structure once the
properties of constituents at the microscopic scale are known. The average stress and strain is mathematically expressed as [49]

\[
\Sigma = \frac{1}{V} \int \sigma_{ij} dV \tag{4.1}
\]

\[
E = \frac{1}{V} \int \epsilon_{ij} dV \tag{4.2}
\]

![Fig. 4.1: Schematic Representation of Unit Cell](image)

4.2 Finite Element Formulation

The principle of virtual work is applied to derive the general finite element equations, which is defined as [49]

Among all admissible configurations of a conservative system, those that satisfy the equations of equilibrium make the potential energy stationary with respect to small admissible variations of displacement.
The minimization of potential energy $\delta \Pi = \delta U - \delta W$ results in

$$\delta U = \delta W$$  \hspace{1cm} (4.3)

where $\delta U$ is internal strain energy and $\delta W$ is external work done given by Equation 4.4 and 4.5 respectively.

$$\delta U = \iiint_V \delta \varepsilon^T \sigma dV$$  \hspace{1cm} (4.4)

$$\delta W = \iint_S \delta \psi_s^T T dS + \iiint_V \delta \psi^T X dV + \delta d^T P$$  \hspace{1cm} (4.5)

where $\delta \varepsilon, \delta d, \delta \psi_s, \delta \psi$ vector of virtual strains, virtual nodal displacements, virtual displacement function $\delta u, \delta v, \delta w$ and virtual displacement functions acting over surface $P, X, T$ are vectors of applied nodal loads, body forces and surface tractions. $\psi = Nd$ and $\psi_s = N_s d$, $\varepsilon = Bd$ and $\sigma = D \varepsilon$. Substitution of Equation 4.4 and 4.5 in Equation 4.3 results in

$$\delta d^T \iiint_V B^T D BdV d = \delta d^T \iint_S N_s^T T dS + \delta d^T \iiint_V N^T X dV + \delta d^T P$$  \hspace{1cm} (4.6)

Neglecting body forces,

$$[K]d = [P] + [f_s]$$  \hspace{1cm} (4.7)

where stiffness matrix $[K] = \iiint_V B^T D BdV$

and $[P]$ is load vector

Equivalent nodal loads due to surface forces $[f_s] = \iint_S N_s^T T dS$

**Lagrange Multipliers to Enforce Constraints**

The minimization of a potential energy subjected to constraint was solved using the Lagrange multiplier method. Mathematically, the problem was addressed as shown in Equation 4.8, where constraint equation $G$ is added to the potential energy.

$$L = \Pi + \lambda G$$  \hspace{1cm} (4.8)
where $L$ is the Lagrangian function, $II$ is potential, $\lambda$ is Lagrange multiplier and, $G = [C]d - [Q]$ is constraint equation. Minimization of Lagrangian with respect to 'd', i.e. $\frac{\partial L}{\partial d} = 0$ and $\lambda$ i.e. $\frac{\partial L}{\partial \lambda} = 0$ results in the system of equations put in broad form [49], as shown in Equation 4.9.

$$\begin{bmatrix} K & C^T \\ C & 0 \end{bmatrix} \begin{bmatrix} d \\ \lambda \end{bmatrix} = \begin{bmatrix} P \\ Q \end{bmatrix}$$  \hspace{1cm} (4.9)

**Hexahedral Element**

A Hexahedral element, also known as 8-noded brick element, is one of the 3D discretized elements frequently used in the finite element analysis of a structure. Each node in this element is associated with three degrees of freedom $u, v, w$ in $x, y, z$ directions respectively as shown in Figure 4.2.

![Fig. 4.2: Hexahedral Element](image)

The associated shape functions for the element, with $r_i, s_i, t_i$ as the values of natural coordinates:

$$N_i = \frac{1}{8}(1 + rr_i)(1 + ss_i)(1 + tt_i) \hspace{1cm} (4.10)$$
The Jacobian and B matrix were computed as:

\[
\begin{bmatrix}
  x_r & y_r & z_r \\
  x_s & y_s & z_s \\
  x_t & y_t & z_t 
\end{bmatrix}
= \sum
\begin{bmatrix}
  N_{i,r}x_i & N_{i,r}y_i & N_{i,r}z_i \\
  N_{i,s}x_i & N_{i,s}y_i & N_{i,s}z_i \\
  N_{i,t}x_i & N_{i,t}y_i & N_{i,t}z_i 
\end{bmatrix}
\]  

(4.11)

where \(\{\Gamma\}\) is inverse Jacobian matrix. The numerical computation of the stiffness matrix for a single element is written as

\[
[K] = \int_{-1}^{1} \int_{-1}^{1} \int_{-1}^{1} B^T DB |J| dr ds dt
\]  

(4.13)

Average stress in numerical form is written as

\[
\Sigma = \frac{\sum_{k=1}^{No of Elem} \sigma_{ij}^k}{V}
\]  

(4.14)

Average strain in numerical form is written as

\[
E = \frac{\sum_{k=1}^{No of Elem} \epsilon_{ij}^k}{V}
\]  

(4.15)

Algorithm:

2. Compute stiffness matrix of each element.

3. Assembling stiffness matrix of whole structure.

4. Partitioning of stiffness matrix into known and unknown degrees of freedom.

5. Solving system of equations using 'UMFPACK' algorithm in SCILAB.

7. Computing average stress and strain of the unit cell.

4.3 Boundary Conditions

In order to obtain the macroscopic properties of the cell wall layer and unidirectional fiber composite, the unit cell was subjected to four load cases: axial, transverse, longitudinal shear and transverse shear, as the material is transversely isotropic. For axial and transverse loading, a quarter model was selected due to its symmetry, as shown in Figure 4.3(a). Transverse shear was simulated by applying periodic boundary conditions to the 2D model as shown in Figure 4.3(b). The boundary conditions applied to the unit cell as explained in [46] are described in Table 4.1.

For longitudinal shear, the face at $y=0$ is fixed and the displacement $U_x, U_y, U_z$ on the faces $x=0$ and $x=a$ are kept same. To obtain shear modulus, a constant displacement is applied on the face $y=a$ in the x-direction (shear loading). $[U_y, U_z]$ on $L = [U_y, U_z]$ on $R$; $[U_y, U_z]$ on $T = [U_y, U_z]$ on $B$ are the periodic boundary conditions in the case of transverse shear as shown in Figure 4.3(b), where L, R, T and B stand for left, right, top and bottom surfaces respectively and the periodic boundary conditions are applied to all the nodes on these surfaces. To simulate transverse shear, a displacement of delta $y$ is applied at $(a, h)$.

4.4 Effective Properties of Cell Wall Layers in Bast Fiber

At the mesoscopic scale, all the bast fibers possess a bundle of laminated tube-like structures (Figure 3.2(b)) called cell walls. Each cell wall is made of Primary, Secondary S1, S2 and S3 layers and mechanical properties of each constituent in these layers are given in Table 4.2. The thickness of each layer differs from the others with S2 layer occupying 80% of the total thickness of the cell wall [51]. The thicknesses of each layer in a cell wall, obtained from [51], are presented in Table 4.3.

The purpose of this section is to evaluate the effective properties (independent elastic constants) of a secondary cell wall layer with a varying volume fraction of basic constituents (C, HC, L). The volume fraction of basic constituents in different bast fibers are given in [52]. Some volume fraction combinations chosen for the analysis are given in Table 4.4. There are

The number of combinations possible and it is impractical to determine the effective properties for each combination through numerical experiments. From the structural point of view, the orientation of fibrils, volume fraction and geometry of constituents are all that is required to evaluate the effective properties. A schematic representation of cell wall layers with constituents is shown in Figure 4.4. The shape of cellulose and arrangement of constituents are of significance in the analysis. The shape of cellulose was found to be square with the work carried out by O’Sullivan [53]. Regarding the arrangement of these constituents, the results presented by Salmen and Preston [54] are also of importance.

Fig. 4.4: Basic Constituents in Cell Wall Layer

Geometry and Meshing

The full 3-dimensional unit cell geometry of the cell wall layer is shown in Figure 4.5. All the constituents are assumed to be square in shape. This assumption results in transversely isotropic properties of an equivalent material with five independent elastic constants. Therefore, five numerical tests were performed to obtain five independent elastic constants. The unit cell geometry was created in the Gmsh meshing software. Gmsh is a 3D mesh generator software developed by Geuzaine and Remacle[55] with the capability of meshing 2D and 3D geometries using different kinds of elements. The Gmsh code was written to create the geometry of a unit cell with a specified mesh size. Also, Gmsh facilitates the option of selecting the number of elements/division along the line during discretization. The application of periodic boundary conditions requires the nodal points to be exactly on the opposite face. Orderly numbering and transfinite algorithms are built-in functions of Gmsh software, facilitating the use of the structured meshes required to implement periodic boundary conditions. The mesh file .msh was generated from Gmsh, which comprises nodal coordinates and element connectivity. A pseudo code is shown in Table 4.5) and the mesh
file .msh for a simple geometry is presented in Appendix Table ??.

Fig. 4.5: 3D Unit Cell Geometry

Fig. 4.6: Node Numbering of Unit Cell Geometry

The 3D quadrant model created to simulate axial and transverse load case is shown in Figure 4.7. The geometry of the longitudinal shear model is similar to the one shown in Figure 4.5.

**FE Analysis and Results**

A 3D finite element code was developed in a SCILAB environment, which requires an input file .msh generated from Gmsh, to compute the effective properties. The input files required to run finite element analysis were generated by the program created to read .msh file as shown in Appendix C.1 and boundary conditions (constraints) were generated by the code sortingsurface.sci (Appendix C.3). The full 3D FE code is presented in Appendix C.4. A finite element code was run for each load case, according to the boundary conditions specified in the previous section. Stress and displacement contour obtained for each load case are shown in Figure 4.8-4.10. The computed elastic constants through the 3D finite element unit cell model are compared with those values presented in [51] and semi-empirical relations given in Equations 4.16-4.19. Comparisons of elastic constants with various methods are
presented in Tables 4.6-4.8, corresponding to each secondary layer and Figure 4.11-4.14.

Fig. 4.8: Axial Load Case

Fig. 4.9: Transverse Load Case

Fig. 4.10: Longitudinal Shear Loading
Semi-Empirical Equations:

Rule of Mixtures:

\[ E_{11} = V_C E_{11}(C) + V_{HC} E_{11}(HC) + V_L E_{11}(L) \]  
(4.16)

Tsai-Hahn Empirical Relation:

\[ \frac{1}{E_2} = \frac{1}{V_f + \eta V_m} \left( \frac{V_f}{E_f} + \eta \frac{V_m}{E_m} \right); \eta = 0.5 \]  
(4.17)

\[ \frac{1}{G_{12}} = \frac{1}{V_f + \eta V_m} \left( \frac{V_f}{G_f} + \eta \frac{V_m}{G_m} \right); \eta = 0.5 \left( 1 + \frac{G_m}{G_f} \right) \]  
(4.18)

Halpin-Tsai Empirical Relation:

\[ \frac{E_f}{E_m} = \frac{1 + \eta \Psi V_f}{1 - \eta V_f}; \eta = \frac{\gamma - 1}{\gamma + \Psi}; \gamma = \frac{E_f}{E_m}; \]  
(4.19)

The Young’s modulus in the axial direction and Poisson’s ratio computed by all the methods are in good agreement and match exactly with the Rule of Mixtures. Transverse modulus compared from the Tsai-Hahn relation is in good agreement with 3D FE results, whereas the multi-pass homogenization procedure gives an error of 17%. The Halpin-Tsai relation involves a parameter that is dependent on the geometry of the fiber and can be derived if the exact results are known. Here the values compared in the Table 4.6-4.8 are computed using \( \Psi = 2 \) and the error was observed to be around 7%. Based on 3D results and through inverse calculations, \( \Psi \) was found to be 1.58 for the transverse modulus and 0.9 for the shear modulus in this particular problem. The Tsai-Hahn equation, in conjunction with the Rule of Mixtures, results in the elastic constants approximate to 3D results. After validating the existing semi-empirical relations with those of the 3D results for a set of combinations, these equations can be directly applied to derive effective elastic constants.

Given any natural fiber, the geometric parameters that play a major role in the cell wall tube properties are: micro fibril orientation, thickness of each layer and the cross-sectional shape. In the next section, the micro fibril orientation in the S2 layer and volume fraction of the constituents were varied to obtain the effective properties of composite.

4.5 Effective Properties of Unidirectional Composite

The properties of the cell wall layers obtained in previous section were used in the second step of homogenization which was carried out at mesoscopic scale. The elastic constants of each layer in a cell wall for various volume fractions of basic constituents were used in performing parametric modeling of the unit cell of unidirectional kenaf fiber composite properties. It was assumed that the bond between matrix and fiber was perfect and the fibers were straight (without any flaws) in the finite element analysis of a unit cell. The fiber volume fraction was considered to be 22% in this analysis as the experiments were carried out at the same volume fraction.

Geometry and Meshing

The cell wall geometry was assumed to be hexagonal in shape with the dimensions adopted from [50] and shown in Table 4.3. The basic geometrical parameters required to create hexagon is shown in Figure 4.15. The parameter $\theta$ in the Gmsh code is a shape factor, meaning that at $\theta = 30^\circ$ the geometry of the cell wall is a regular hexagon and changes to an irregular hexagon at other $\theta$ values. A fiber geometry consisting of a bundle of seven cell walls and the periodic arrangement of fibers in the matrix was created in Gmsh is shown in Figure 4.16 and 4.17 respectively. The unit cell geometry meshed with hexahedral elements is shown in Figure 4.18. As the properties obtained were invariant of length (Z-dir), the unit cell thickness and number of elements in thickness direction was kept about (1/10)th of cross-sectional dimension, which reduced the computation effort.
Fig. 4.15: Basic Hexagonal Shaped Cell

\[ P = [A + B \sin(\theta), 0]; \quad Q_1 = Q + \left[ \frac{T}{\tan(\theta_1)}, T \right] \]
\[ P_1 = P + \left[ \frac{T}{\cos(\theta)}, 0 \right]; \quad R = [0, B \cos(\theta)]; \]
\[ Q = [A, B \cos(\theta)]; \quad R_1 = R + [0, T]; \]

Fig. 4.16: Schematic Representation of Bundle of Cell Walls
The secondary layers of the cell wall consist of micro fibrils with orientations varying as follows: S1:50°-70°, S2:0°-30°, S3:60°-80°. A finite element analysis by Qing et al. [50], concluded that the fiber properties in the axial direction were strongly influenced by the S2 layer properties. Therefore, only S2 layer micro fibril orientation was varied from 0° to 30° with an interval of 5°, whereas the S1 and S3 layer orientation was fixed as 70° and 80° respectively throughout the analysis. The effect of S1 and S3 micro fibril orientation on the transverse modulus was observed to be minimal (5%) [50]. In this section, for varying volume fractions of basic constituents (Table 4.4), the MFA in the S2 layer was varied and FE analysis was carried out to obtain the macroscopic properties of the unit cell shown in Figure 4.18. As explained in [50], for layer S1 and S3, the bidirectional reinforcement was considered and the properties of these layers were calculated in a similar way. The properties are listed in Table 4.10.

Augmented Lagrange Method

The Lagrange multipliers method introduces more equations (equal to constraint equations) to the stiffness matrix and the diagonal terms of the matrix go to zero, implying that the matrix becomes nearly singular. Therefore, an Augmented Lagrange method was applied to obtain a new stiffness matrix, that is a combination of penalty and Lagrange multiplier methods and was solved for displacements. The potential energy functional with perturbed constraint equation is given by

\[
\Pi = \frac{1}{2} D^T K D - D^T F + \frac{1}{2} \alpha (\text{penalty function} - \text{perturbation})^2
\]

Let \( g(D) \) be the penalty function ([C][D]-[Q]=0) and \( \delta \) is perturbation

\[
\Pi = \frac{1}{2} D^T K D - D^T F + \frac{1}{2} \alpha (g(D) - \delta)^2
\]

After expansion of the third term and neglecting delta square term, the final equation takes the following form:

\[
\Pi = \frac{1}{2} D^T K D - D^T F + \frac{1}{2} \alpha g^T \alpha g - g^T \alpha \delta
\]

replacing \( \alpha \delta \) by \( \lambda^T \)

\[
\Pi = \frac{1}{2} D^T K D - D^T F + \lambda^T g + \frac{1}{2} g^T \alpha g
\]

The first three terms represents the Lagrange multiplier formulation and fourth term is the penalty function augmented. Minimization of potential w.r.t \( D \) results in

\[
[K + C^T \alpha C] D = F + C^T \alpha Q - C^T \lambda^P
\]

and considering the last two terms of Equation 4.23 as equivalent to Lagrange formulation

\[
\lambda^P = \lambda^i + \alpha g(D)
\]
Algorithm to obtain $\lambda$

1. Input: $\alpha$ (penalty factor), tolerance

2. While $\lambda - \lambda^p \leq$ tolerance
   { Calculate $D$ using Equation 4.24
     Substitute $D$ in Equation 4.25 to obtain updated $\lambda$ value. }

(a) Shear Stress in ZX

(b) Displacements

Fig. 4.21: Longitudinal Shear

**Transverse Shear Simulation**

The transverse shear properties of a composite were obtained by subjecting the unit cell to the periodic boundary conditions, as explained in [46]. The implementation of periodic boundary conditions involves the nodes on opposite faces (i.e. i-j and k-l) as shown in Figure 4.22. These nodes were subjected to same displacements. In order to prevent rigid body motion during the finite element simulation, the following boundary conditions were imposed on the unit cell.

Boundary conditions

$v(x, -b) = v(x, b);$

$u(-a, y) = u(a, y);$

$v(-a, y) = v(a, y) = 0$

$v(-a, -b) = v(a, -b) = v(a, b) = v(-a, b) = 0$

$u(x, b) = \delta; u(x, -b) = -\delta$
Fig. 4.22: Periodic Boundary Conditions for Transverse Shear

The variation of elastic properties as a function of the MFA in the S2 layer are shown in Figure 4.24. The axial modulus of the composite decreased with an increase in MFA of the S2 layer. The transverse modulus and transverse shear modulus were least effected. The transverse modulus decreased by 7%. For the transverse loading case, the maximum stress in y-direction was observed at the point P of the hexagon, as shown in Figure 4.20(a). For the transverse shear load, maximum shear stress was observed on the interface between matrix and cell wall layer P1 and Q1, as shown in Figure 4.23(a).

Fig. 4.24: Effect of MFA on Axial Modulus

Fig. 4.25: Effect of MFA on Macroscopic Elastic Properties

Observation

Increase in MFA

1. The axial modulus reduced by 48-54%.

2. Transverse and shear modulus were least effected.

3. The longitudinal shear modulus increased by 15%.

4. The longitudinal Poisson’s ratio increased by 3% and transverse Poisson’s ratio decreased by 10% due to reduced stiffness in the axial direction.
Increase in Cellulose Content

1. The axial modulus increased by 22% at MFA of zero.

2. The shear modulus and Poisson’s ratio were least effected, with an increase in cellulose content.

4.6 Von-Mises Fisher Probability Distribution

The importance of Von-Mises distributions for directional data is similar to that of normal distribution for linear data [56]. The generalized (p-1) dimensional Von-Mises density function for a vector of observations $X$ can be written as

$$f_{\mu,k,p}(X) = C_p(k)e^{k\mu X} \quad (4.26)$$

where $\mu$ is the mean vector, $k$ is the concentration parameter and $C_p(k)$ is the normalizing factor with the values,

For $p=2$, circle:

$$C_p(k) = 1/(2\pi I_o(k))^2 \quad (4.27)$$

For $p=3$, sphere:

$$C_p(k) = k/(4\pi \sinh(k)) \quad (4.28)$$

For low concentration values of $k < 1$, the distribution is normal on a spherical plot and as the concentration value increased, all the data points were concentrated (green) in one direction, as shown in Figure 4.26.
The purpose of this probability distribution function is to define the orientational distribution of fibers in a composite. The higher the \( k \) value, the more parallel the fibers are to the longitudinal axis, as shown in Figure 4.27(d). The lower the \( k \)-value, the more randomly distributed the fibers are in all directions, as shown in Figure 4.27(a). The derivation of random variables from the Von-Mises Fisher probability distribution function is explained below:

**Derivation of random variables**

Probability density function

\[
f(\theta) = \frac{k}{2 \sinh(k)} e^{k \cos(\theta)} \sin(\theta) \quad ; g(\phi) = \frac{1}{2\pi}
\]

Cumulative distribution function

\[
\xi = \frac{ke^{-k}}{1 - e^{-2k}} \int_{-\pi}^{\theta} e^{k \cos(\theta)} \sin(\theta) \, d\theta
\]

After evaluating integral in WxMaxima and performing inverse,
\begin{equation}
\theta = 2 \sin^{-1} \left[ \sqrt{-\log \left( \xi \left(1 - \lambda \right) + \lambda \right)} \right] / 2k
\end{equation}

where \( \lambda = e^{-2k} \)

To generate random \( \theta \) values for a particular concentration factor \( k \), a uniformly distributed random number vector \( \xi \) is given as an input to the Equation 4.31. The PDF obtained for different concentration values is shown in Figure 4.28. A SCILAB program was written to generate the randomly oriented cylindrical fiber in a bounded cube, where the orientation is controlled by a factor \( k \).

(a) Random Fiber Distribution \( k=1 \)

(b) Random Fiber Distribution \( k=10 \)

4.7 Equivalent Properties of Randomly Oriented Short Fiber Composite

The orientational averaging technique was explained in the work done by [57] to obtain the properties of random fiber composite. Some of the other works related to orientation averaging can be seen in [58-62]. In this section, the Von-Mises probability distribution is considered for use in obtaining properties of random short fiber composite. The concentration parameter for the distribution is in a selected range of 0.5 to 80, explaining fiber orientation in a particular direction to random. The properties for various volume fractions were considered, and the orientation averaging technique was applied to each of them respectively.

Orientational Averaging
The orientational averaging technique to obtain effective elastic modulus was derived by Christensen and Waals [57]. The various empirical relations for predicting the elastic modulus of a 2D and 3D randomly oriented short fiber composite was presented by [62]. The idea behind orientational averaging technique is to obtain the average of unidirectional fiber composite properties for all possible orientations. Mathematically, the orientation averaging is expressed as:

\[
\frac{\sigma'_{ij}}{\varepsilon'_{ij}} = \frac{\int \int_0^\pi \sigma'_{ij} (pdf) \sin(\theta) \, d\theta \, d\phi}{\int \int_0^\pi \sin(\theta) \, d\theta \, d\phi}
\]  

(4.32)

Assuming that the fiber is cylindrical and oriented in 3 dimensional space, as shown in Figure 4.29, with 123 as a rotated coordinate system and 1’2’3’ as a fixed coordinate system. If the composite properties is transversely isotropic with fiber oriented along 1-axis, the constitutive relation in transformed axis is given by \( CM = \lambda_{ij} C' \lambda'^T_{ij} \)
\[ \lambda = \begin{bmatrix} a^2 & b^2 & c^2 & 2ab & 2ac & 2bc \\ d^2 & e^2 & f^2 & 2de & 2df & 2ef \\ g^2 & h^2 & i^2 & 2gh & 2gi & 2ih \\ ad & be & cf & ae + bd & af + cd & bf + ce \\ ag & bh & ci & ah + bg & ai + cg & bi + ch \\ dg & eh & fi & dh + eg & di + fg & ei + fh \end{bmatrix} \]

\[ (4.33) \]

\[
\begin{bmatrix} a & b & c \\ d & e & f \\ g & h & i \end{bmatrix} = \begin{bmatrix} \sin(\theta) \cos(\phi) & -\cos(\theta) \cos(\phi) & \sin(\phi) \\ \sin(\theta) \sin(\phi) & -\cos(\theta) \sin(\phi) & -\cos(\phi) \\ \cos(\theta) & \sin(\theta) & 0 \end{bmatrix} \]

\[ (4.34) \]

\[ C = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{22} & C_{23} & 0 & 0 & 0 \\ C_{33} & 0 & 0 & 0 \\ C_{44} & 0 & 0 \\ C_{66} & 0 \end{bmatrix} \]

\[ (4.35) \]

The relation between \( \sigma_{33} \) and \( \epsilon_{33} \), \( \sigma_{22} \) and \( \epsilon_{33} \) for an arbitrarily applied \( \epsilon_{33} \) were given by

\[
\frac{\sigma'_{33}}{\epsilon_{33}} = C_{11} \cos^4 \theta + (2C_{12} + 4C_{66}) \cos^2 \theta \sin^2 \theta + C_{22} \sin^4 \theta
\]

\[ (4.36) \]

\[
\frac{\sigma'_{22}}{\epsilon_{33}} = C_{11} d^2 g^2 + C_{12} (d^2 h^2 + e^2 g^2 + d^2 f^2) + C_{22} e^2 h^2 + 4C_{66} ghde + C_{23} h^2 f^2
\]

\[ (4.37) \]

\[
\frac{\sigma'_{33}}{\epsilon_{33}} = \frac{1}{15} (3C_{11} + 4C_{12} + 8C_{22} + 8C_{66})
\]

\[ (4.38) \]

\[
\frac{\sigma'_{22}}{\epsilon_{22}} = \frac{1}{15} (C_{11} + 8C_{12} + C_{22} - 4C_{66} + 5C_{23})
\]

\[ (4.39) \]
For a normal distribution, pdf=1 and the orientational averaging results in Equations 4.39 and 4.38 in 2 and 3 directions respectively.

Assuming the behavior of a randomly oriented composite to be quasi isotropic, the equivalent relation to the Equations 4.39 and 4.38 were written as

\[
\frac{\sigma_{33}'}{\varepsilon_{33}'} = \frac{(E(1-\nu))}{((1-2\nu)(1+\nu))} \tag{4.40}
\]

\[
\frac{\sigma_{22}'}{\varepsilon_{22}'} = \frac{(E\nu)}{((1-2\nu)(1+\nu))} \tag{4.41}
\]

Equating 4.39 and 4.41, 4.38 and 4.40 and solving the equations will result in equivalent elastic properties \(E\) and \(\nu\). The Von-Mises Fisher probability density function was chosen to calculate the average macroscopic properties of a random oriented composite with varying concentration parameters, as explained in the previous section. For the purpose of analysis, concentration parameters of \(k=0.5, 2, 5, 8, 10, 20, 40, 60, \) and 80 were chosen. The transverse isotropic properties evaluated on the unit cell as explained in Section 4.5 for various volume fractions of basic constituents were substituted in the constitutive relation given in the Equation 4.35 and average value of elastic modulus and Poisson’s ratio were calculated according to the procedure explained in Equations 4.38 to 4.41. The evaluated elastic constants for the volume fraction of 50/27/23 is shown in Table 4.35 and the values of remaining volume fraction are presented in Appendix A.5-A.8.

Fig. 4.30: Equivalent Young’s Modulus With Varying Concentration Factor
4.7.1 Observations

1. The finite element model for unidirectional composite properties was based on the assumption that the bond between fiber and matrix was perfect.

2. From the graph Figure 4.30-4.31, it was deduced that the concentration factor of 0.5 and 2 suggests more random fiber orientation and quasi isotropic properties. That is, properties were least affected by the MFA orientation.

3. The range of equivalent Young’s modulus obtained through orientation averaging was 5.3-6.34 GPa, whereas the mean Young’s modulus evaluated from tensile test was 6.48 GPa.

4. The increase in concentration factor $k$ resulted in direction dependent effective properties. The Poisson’s ratio remained almost same for varying cellulose content.
Chapter 5
Summary, Conclusion, and Future Work

5.1 Summary of Work Performed

As a part of this dissertation, the micro-structure of kenaf fiber was explored using an optical microscope and a scanning electron microscope. Defects such as fiber damage, variation in the fiber width along axial direction, and delamination were observed (Figure 3.3). The images of the kenaf fiber obtained from the scanning electron microscope revealed one of the cell wall shapes to be a hollow rectangle Figure 3.2(b), whereas in general the cell wall shapes were an irregular polygon, as observed from the optical microscope images as shown in Figure 3.1. In order to obtain the tensile modulus of kenaf fiber, a tensile test was performed using the Instron 5848 testing machine. To study the influence of fiber gage length on the tensile modulus, four different gage lengths of 10, 15, 20 and 25.4 mm were selected and ten fibers in each lot were tested. The approximate cross-sectional area of fiber after failure was measured using an optical microscope. The procedure used to prepare the sample for microscopy examination was discussed in section 3.2.2. ImageJ software was used to evaluate the fiber cross-sectional area of the images obtained from the optical microscope at 50X magnification.

The kenaf fiber composite sample was processed by mixing chopped kenaf fibers and epoxy matrix using a vacuum bagging technique in the first attempt. Before preparing the composite, the chopped kenaf fibers were rinsed in a 3% sodium hydroxide solution to remove surface impurities and shredded using carding brushes. The vacuum bagging technique resulted in a composite plate with an uneven surface that was not suitable for tensile tests. Therefore, in the second attempt composite samples (dimensions as per ASTM D638) were prepared in HDPE molds by applying pressure through clamps and cured at 80°C. Tensile tests were conducted on the composite samples to obtain Young's modulus and
Poisson’s ratio. Fourteen samples were tested on the Tinius Olsen tensile testing machine and force and strain data were acquired through NIDAQ 9237, for which a LabVIEW code was written, as shown in Figure B.3.

A 3D finite element code was written in a SCILAB environment to calculate the homogenized or effective properties of the natural fiber composite. A two-step homogenization was carried out: the first step obtained the properties of the cell wall layers at the microscopic scale and the second obtained unidirectional natural fiber composite properties. To avoid an ill-conditioned matrix that appeared due to the number of constraint equations, an augmented Lagrange technique was applied in the finite element code. To create a geometric model, Gmsh 3D mesh generator software was used, which provided an advantage of the structured mesh. In the final step of modeling, an orientational averaging technique was applied to evaluate the random fiber composite properties using the Von-Mises Fisher probability distribution function, as explained in section 4.6.

5.2 Summary of Findings and Conclusion

Micro-structure of Kenaf Fiber

1. The optical microscopic images of kenaf fibers obtained along the fiber axial direction exhibited defects such as delamination between cell walls, varying width, damage of fiber and sudden reduction in cross-sectional area. This lead to varying tensile strengths of kenaf fiber due to the amount of defects present based on the weakest links theory.

2. The cross-sectional images obtained through the optical microscope and the scanning electron microscope revealed the irregular cell wall shape and the hollow portion of the cell wall. Therefore, an appropriate cross-sectional area was required to evaluate stress in the fiber, taking into account the voids present on the cross-section. The cross-sectional area of the kenaf fiber measured after tensile test had an equivalent circular diameter of 45 µm on average.

Influence of Gage Length on Kenaf Fiber Modulus
1. The tensile behavior of kenaf fibers was observed to be linear and failure to be brittle.

2. The tensile modulus of kenaf fiber was seen to increase with an increase in gage length. This might be due to inconsistent micro-structure, accurate cross-sectional area for evaluating stress and effective gage length in strain calculations. It can be concluded that to evaluate the Young’s modulus of a kenaf fiber, a minimum gage length of 25.4 mm or more should be adopted.

3. The Weibull method was applied to characterize the tensile strength of a kenaf fiber. Two parameter, three parameter and Weibull of Weibull models were used to fit the tensile strength data. The average tensile strength obtained from the Weibull of Weibull model was observed to be in good agreement with the experimental values. In order to obtain appropriate Weibull distribution fit, more samples should be tested.

Tensile Properties of Randomly Oriented Kenaf Fiber Composite

1. The kenaf fiber composite exhibited linear behavior and brittle failure with the tensile strength in the range of 20-38 MPa, as presented by other researchers in the past. The tensile strength is very low compared to that of the neat resin due to the amount of tensile strength reducing voids present in the composite.

2. The Poisson’s ratio varied from specimen to specimen and was found to be in the range of 0.28-0.43. A possible reason for this might be the fiber orientation and inconsistent micro-structure at the point where the strains were measured.

3. The mean Young’s modulus of the kenaf fiber composite at 22% fiber volume fraction is 6.48 GPa and comparative to the glass fiber composite of 7-8 GPa. This is an evidence that the kenaf fiber composite can replace glass fiber composite in terms of elastic modulus.

Numerical Modeling of Natural Fiber Composite

1. The Youngs modulus in the axial direction and Poisson’s ratio computed using 3D finite element and semi-empirical relations presented in Section 4.4 were observed
to be in good agreement with the Rule of Mixtures. The transverse modulus was observed to be in good agreement with Tsai-Hahn empirical relation, whereas results from the multi-pass homogenization procedure gave an error of about 17%. Through inverse calculations, parameter $\chi$ of Halpin-Tsai empirical relation was seen to be 1.58 for the transverse modulus and 0.9 for the shear modulus.

2. The homogenized properties of an unidirectional kenaf fiber composite were obtained using parametric finite element modeling, with varying micro-fibril orientation in S2 layer. The axial modulus was reduced by 48-54% with an increase in MFA in the S2 layer. The transverse modulus and shear modulus were least affected. The axial modulus increased by 22% with an increase in cellulose content at MFA of $0^\circ$. The shear modulus and Poisson’s ratio were least affected by an increase in cellulose content. These results indicate that the axial modulus of a composite is a function of fiber anisotropy. The numerical tests shows that the axial modulus increases with an increase in the cellulose content and the composites processed from fibers like cotton and ramie (which constitute 90% cellulose) as reinforcement will have increased Young’s modulus as.

3. It was deduced that the composite properties remained quasi-isotropic at the concentration parameter of 0.5 and 2 (i.e. equivalent modulus remained almost constant) as shown in Figure 4.30. With an increase in the concentration parameter, the equivalent modulus appeared to be direction dependent (i.e. it decreases with an increase in MFA). The homogenization model developed for randomly oriented short fiber composite was able to predict the equivalent modulus (material is quasi-isotropic) and also explained the direction dependence property with fibers oriented in a particular direction.

5.3 Future Work

1. Understanding fiber and matrix interfacial characteristics through fiber pull out tests/single fiber fragmentation tests will provide an opportunity for enhancing the strength
of natural fiber composites.

2. The appropriate manufacturing method for reducing the voids will enhance the strength of composites.

3. The application of kenaf fiber reinforced composites becomes crucial in the hygroscopic environment due to fiber water absorption property. Therefore, durability studies will be required to understand the behavior of the composite.

4. The voids in the unit cell and an imperfect bond (interface model) between fiber and matrix will be required to model the fracture and damage behavior of the composite.
