Abstract. Most mercury pollution is emitted to the atmosphere, and the location and bioavailability of deposited mercury largely depends on poorly understood atmospheric chemical reactions that convert elemental mercury into oxidized mercury compounds. Current measurement methods do not speciate oxidized mercury, leading to uncertainty about which mercury compounds exist in the atmosphere and how oxidized mercury is formed. We have developed a gas chromatography/mass spectrometry (GC-MS)-based system for identification and quantification of atmospheric oxidized mercury compounds. The system consists of an ambient air collection device, a thermal desorption module, a cryofocusing system, a gas chromatograph, and an ultra-sensitive mass spectrometer. It was able to separate and identify mercury halides with detection limits low enough for ambient air collection (90 pg), but an improved ambient air collection device is needed. The GC/MS system was unable to quantify HgO or Hg(NO₃)₂, and data collected cast doubt upon the existence of HgO in the gas phase.

1 Introduction

Mercury (Hg) emitted in the gas phase can remain in the Earth’s atmosphere for many months and be transported around the globe (Lindberg et al., 2007). Atmospheric Hg pollution is a global problem, and regulation of Hg emissions exist at the state, national, and international levels (Selin, 2009). Hg pollution arises from a variety of natural and anthropogenic point and nonpoint sources (Gustin et al., 2008; Seigneur et al., 2004). Hg can exist in the atmosphere as elemental Hg (Hg⁰), or as various oxidized Hg compounds (HgII) (Lyman et al., 2010a). Most mercury is emitted to the atmosphere as Hg⁰ (Pacyna et al., 2006), but it can be oxidized to HgII in the atmosphere, and HgII can be reduced to Hg⁰ (Hedgecock and Pirrone, 2004). HgII can be found in both the particulate-bound (HgIIp) and gaseous forms (HgIIG) (Sprovieri et al., 2010) and is water-soluble and semi-volatile (Gustin et al., 2008; Lindberg et al., 2007). As a result, aerosols and clouds readily absorb HgIIG, and it is also readily dry deposited (Holmes, 2012; Lyman et al., 2007). Lyman and Jaffe (2012) and others (Gratz et al., 2015; Slemeer et al., 2009; Talbot et al., 2007) report that the upper troposphere and lower stratosphere are depleted in Hg⁰ and enriched in HgII, and oxidation of Hg⁰ to HgII has also been shown to occur in the marine boundary layer (Wang et al., 2014) and the Arctic during springtime (Steffen et al., 2008). The location and timing of Hg deposition to ecosystems depends on atmospheric chemistry and the form of Hg in the air (Gustin et al., 2013b; Holmes et al., 2010; Lin et al., 2006; Lyman and Gustin, 2008; Lyman et al., 2010a).

In 1974, Johnson and Braman (1974) suggested that oxidized Hg might consist of HgO and/or Hg halides, and most current studies still echo this hypothesis (Ariya et al., 2009; Holmes et al., 2010; Hynes et al., 2009; Lin et al., 2006). HgO could be produced by the reaction of Hg⁰ with ozone (Pal and Ariya, 2004b), OH (Pal and Ariya, 2004a), or NO₃ (Sommar et al., 1997). Evidence exists for the involvement of NO₃ in formation of HgII (Peleg et al., 2015). Some have argued that HgO is likely to exist only as HgIIG (Calvert and Lindberg, 2005; Shepler and Peterson, 2003) and that oxidation of Hg⁰ by ozone may produce an HgO₃ intermediate which could decompose to HgO on particles (Calvert and Lindberg, 2005) or react with water to form Hg(OH)$_2$ (Tos-
is likely that most atmospheric Hg in rainwater is methylated (Lindberg et al., 2007), and it sphere may be methylmercury, but less than 3 % of oxidized Wilcox and Blowers, 2004). Some oxidized Hg in the atmos- 
phere radicals have also been implicated as potential Hg oxidants in the marine boundary layer (Laurier et al., 2003), the Dead Sea (Obrist et al., 2011), and the free troposphere and strato- 
sphere (Holmes et al., 2006). 

Hg\[^{II}\] emitted from combustion facilities is generally thought to be HgCl\(_2\) (Galbreath and Zygarlicke, 2000; Wilcox and Blowers, 2004). Some oxidized Hg in the atmosphere may be methylmercury, but less than 3 % of oxidized Hg in rainwater is methylated (Lindberg et al., 2007), and it is likely that most atmospheric Hg\[^{II}\] is inorganic. 

Hg\[^{0}\], Hg\[^{II}\], and Hg\[^{II}\] (operationally defined) are measured routinely at dozens of locations around the world. Current measurement methods for Hg\[^{II}\] have been shown to be biased low, however (Gustin et al., 2013a; McClure et al., 2014), and ozone and water vapor have been implicated as inter- ferences (Huang and Gustin, 2015; Lyman et al., 2010b). These measurements have only been calibrated rarely, and development and regular deployment of a field-deployable calibrator has been called for (Gustin et al., 2013b; Jaffe et al., 2014). Current Hg\[^{II}\] instrumentation is also not species-specific, so it does not provide information about the individual compounds that make up measured Hg\[^{II}\] (Jaffe et al., 2014). Different species will have different deposition rates, solubility, and bioavailability (Eagles-Smith and Ackerman, 2014; Peterson et al., 2015), so determining the chemical nature of Hg\[^{II}\] is a critical research priority (Gustin et al., 2013b; Jaffe et al., 2014; Malcolm and Keeler, 2007). Huang et al. (2013b) have developed a thermal desorption system to provide chemical information about Hg\[^{II}\], but other, complimentary methods are also needed.

Unlike the atomic fluorescence method commonly used for measurement of atmospheric Hg, mass spectrometric methods can be used to identify the chemical composition of Hg compounds (Deeds et al., 2015). Further, gas chromatography/mass spectrometry (GC/MS) can allow for separation of individual Hg compounds and separation of Hg compounds from non-mercury components of ambient air samples (Babko et al., 2001; Olson et al., 2002). Inductively coupled plasma mass spectrometry (ICP-MS) is routinely used for measurement of Hg and Hg isotope ratios, but the method is only useful for elemental analysis (dos Santos et al., 2009). GC analysis is routinely used for analysis of organic Hg in various media, and for analysis of Hg\[^{II}\] in water after alkylation of the inorganic Hg compounds (Cavalheiro et al., 2014). However, alkylation destroys the native structure of Hg compounds and thus does not provide information about their original identity.

Babko et al. (2001) showed that GC/MS could be used to separate and identify Hg halides. They injected a solution of HgCl\(_2\) in acetone into a GC/MS and found good recovery and consistent peaks. The detection limits, however, were much higher than would be practical for ambient air analysis. Olson et al. (2002) used GC/MS to identify Hg\[^{II}\] generated by an MnO\(_2\) sorbent in simulated flue gas. They used an impinger to trap the Hg in acetonitrile, then evaporatively concentrated the solution before injecting into a GC/MS. They injected HgCl\(_2\) in acetonitrile and observed mass spectra that were clearly indicative of HgCl\(_2\). They also injected Hg(NO\(_3\))\(_2\) and Hg(NO\(_3\))\(_2\) × H\(_2\)O and saw a similar peak and mass spectra to what they observed in the gas that passed through the MnO\(_2\) sorbent.

We have developed a GC/MS-based system to quantify and chemically identify Hg compounds. We describe this analytical system in detail, provide first results, and discuss remaining challenges.

2 Materials and methods

The GC/MS-based Hg\[^{II}\] detection system consisted of a sample collector to concentrate Hg compounds from the ambient atmosphere, a sample desorber to introduce collected compounds into the gas phase, a cryogenic preconcentrator (cryo- trap) to focus and inject Hg compounds, a gas chromatograph to separate Hg compounds from each other and from possible interferents, and an ultra-sensitive mass spectrom- eter to definitively determine the chemical speciation of Hg compounds (Fig. 1). It also incorporated a permeation system, pyrolyzer, and Hg\[^{0}\] detector to introduce a consistent, quantifiable amount of various Hg compounds to the system in the gas phase. All wetted parts of the system were kept at at least 160 °C (except the sample desorber, which was sometimes cooler), and all wetted parts except the GC columns and VICI GC valve rotors were composed of deactivated fused silica-coated stainless steel. The VICI GC valve rotors were composed of Valcon E (a polyarylether-ketone/PTFE composite).
2.1 Sample collector

Four collection materials were tested for suitability to concentrate volatile Hg compounds in air samples. Collection materials tested were nylon membranes, polydimethylsiloxane (PDMS) sorption tubes, quartz wool-filled tubes, and deactivate fused silica-coated stainless steel. Nylon membranes were Cole-Parmer nylon polyamide membranes (47 mm round, 0.2 µm thick, P/N: EW-36229-04). The PDMS sorption tubes were those for a Gerstel Thermal Desorption Unit (TDU), and were filled with conditioned PDMS foam (P/N: 013758-105-00). Quartz wool-filled tubes were made from 22 cm long × 1.3 cm diameter perfluoroalkoxy (PFA) tubing that was washed with soap and water, soaked for 24 h in a 10% nitric acid bath, rinsed with 18.2 MΩ cm⁻¹ water, then dried in a particle-free environment. The tubing was then filled with quartz wool that had been baked at 800 °C for 2 h to ensure no contamination. Deactivated fused silica-coated stainless steel was a 1 cm length of 0.3 cm tubing.

Selection of the best collection surface was based on presence of identifiable Hg peaks on the GC/MS with the least amount of signal interference. Hg was introduced to the sample collectors either from the permeation oven or by passing outdoor ambient air through the collectors. Ambient air samples were collected from Peavine Peak (latitude 39.590, longitude −119.929) near Reno, Nevada; at the University of Nevada, Reno campus in Reno, Nevada (latitude 39.537, longitude −119.805); and Grizzly Ridge (latitude 40.738, longitude −109.484) near Vernal, Utah, using quartz wool-filled tubes and nylon membranes. Quartz wool-filled tube ambient air samples were collected by pulling air through the tubes at 30 L min⁻¹ for 3 h. Some of the tubes were at ambient temperature during collection, while others were kept at 0 °C. Nylon membranes were collected by pulling air through the membranes at 1 L min⁻¹ for 2 weeks. More information about nylon membrane methods is available from Huang et al. (2013a). All ambient air samples were collected during summer months.

2.2 Sample desorber

A thermal desorption module was used to reintroduce collected compounds into the gas phase. We constructed this module by connecting a lab oven to an adjustable digital temperature controller. Membrane samples were placed within a sample desorption chamber inside the oven, while sample collection tubes were connected directly to the desorption flow path. The desorption chamber was stainless steel coated with deactivated fused silica. A constant flow of ultra-high purity (UHP) Helium (He) acted as a carrier gas to pass volatilized compounds to the cryotrap. The flow of UHP He was controlled at a rate of 30 mL min⁻¹. Desorption temperatures in the range of 80–160 °C were used.

2.3 Cryogenic preconcentrator

The cryogenic preconcentrator (cryotrap) was used to focus desorbed compounds prior to introduction into the GC. A Scientific Instrument Services Model 961 GC Cryo-Trap was used with liquid nitrogen as the cryogen. The cryotrap works by enclosing a portion of the GC column in a small metal cylinder. A flow of liquid nitrogen is passed through the small cylinder at a rate determined by a digital temperature controller. Volatile compounds are retained on the cooled column. After collection, the metal cylinder rapidly heats up via a nichrome wire heating coil, volatilizing concentrated compounds and allowing them to pass into the GC/MS. During this step, the trap temperature is able to increase by 14 °C per second. Cryotrapping temperatures tested ranged from −50 to 30 °C, and heating temperatures tested ranged from 170 to 240 °C. The cryotrap was housed in a lab oven. Lab oven temperatures tested ranged from 160 to 220 °C. A VICI six-port GC valve (Model 4C6WT) was housed within the lab oven and controlled flow of sample to the cryotrap, and from the cryotrap to the GC. A heated line with a deactivated fused silica guard column (0.25 mm internal diameter) was used to connect the cryotrap to the GC.

2.4 Gas chromatograph with an ultra-sensitive mass spectrometer

A Shimadzu GC-2010 Plus gas chromatograph was used to separate Hg compounds from each other and from possible interferents. Different GC column types and lengths were used to test optimum conditions for Hg compound separation. A 30 m low-polarity Restek Rxi-5Sil MS column (5% diphenyl/95% dimethyl polysiloxane), a 60 m ultra-low-polarity Supelco SPB-Octyl fused silica capillary column (50% n-Octyl/50% methyl siloxane), and a 30 m non-polar Restek Rxi-1ms column (100% dimethyl polysiloxane) were tested. GC oven temperatures tested ranged from 140 to 220 °C. After passing through the GC column, the compounds of interest moved to a Shimadzu QP2010 Ultra mass spectrometer for detection of unique chemical signatures of Hg compounds in samples. The MS was operated in high-sensitivity electron impact ionization mode, and included a direct probe inlet. Small quantities of solid-phase Hg compounds were added directly to the MS via to the direct probe inlet to determine representative mass spectra for the compounds.

2.5 Permeation system, pyrolyzer, and Hg detector

Permeation tubes were made to generate four Hg²⁺ compounds (HgBr₂, HgCl₂, Hg(NO₃)₂, and HgO; Sigma-Aldrich, purity 99.9 % or greater). These compounds were packed in permeation tubes constructed of thin-wall 0.3 cm diameter FEP tubing with solid polytetrafluoroethylene (PTFE) plugs in both ends. The permeable length
of each tube was approximately 1 mm. Larger permeation tubes (1.3 cm diameter × 15 cm permeable length) were also tested for Hg(NO$_3$)$_2$ and HgO. Permeation tubes were enclosed within 0.5 cm inner diameter deactivated fused silica-coated stainless steel tubing. UHP He flowed at 30 mL min$^{-1}$ through the stainless steel tubing and over the permeation tubes. The tubes were housed in an oven consisting of an insulated metal box heated to 100 ± 0.1 °C. A VICI multiport GC valve (Model CSF6) selected among four available permeation tubes or passed permeation flow to vent. The multiport valve was housed within the same lab oven as the cryotrap.

A pyrolyzer was used to verify permeation rates of Hg compounds. The pyrolyzer consisted of a 2.5 cm diameter × 18 cm length quartz tube packed with quartz wool. The quartz tube was wrapped with nichrome wire that was used with a variable voltage controller to control the temperature of the tube. The pyrolyzer was kept at 800 °C to convert Hg compounds to Hg$^0$ as they passed from the permeation oven through the quartz tube. Hg$^0$ concentrations were measured downstream of the pyrolyzer using a Tekran 2537 mercury vapor analyzer.

2.6 Hg compound transmission tests

We permeated HgBr$_2$ into a 1 cm diameter PFA manifold to test the ability of different materials to transmit Hg compounds (Fig. S1 in the Supplement). The manifold was heated to 100 °C. Air scrubbed of Hg via an activated carbon cartridge was drawn through the manifold at 10 L min$^{-1}$. A tee pulled a 1 L min$^{-1}$ subset of air from this manifold into a Tekran 2537/1130 speciation system with a KCl-coated denuder, which measured Hg$^0$ and Hg$^{II}$. The tee to the denuder was 100 cm downstream of the point where HgBr$_2$ was added to the manifold air. One of several 15 cm long × 0.3 cm diameter tubes was placed between the manifold and the Tekran speciation system to test the ability of these tubes to transmit HgBr$_2$. These 15 cm tubes were constructed of different materials, including stainless steel, PFA (as a control, since the entire manifold was PFA), PEEK, and deactivated fused silica-coated stainless steel. Fittings used to secure the 15 cm tubes were of the same materials as the tubes. The 15 cm stainless steel, PFA, PEEK, and deactivated fused silica-coated stainless steel tubes were each tested for 24 h. The Tekran system collected one measurement every 1.5 h, so approximately 16 samples were obtained for each experimental condition.

3 Results and discussion

We initially identified HgBr$_2$ and HgCl$_2$ via the method utilized by Babko et al. (2001), which was to dissolve the compounds in acetone and inject the solution into a splitless inlet at 200 °C. We used a non-polar 100 % PDMS column at 160 °C for separation. We were able to separate HgCl$_2$ from HgBr$_2$ with this system (Fig. 2). The relative abundance of Hg isotopes in Fig. 2 is similar to isotopic abundances reported by IUPAC (de Laeter et al., 2004), confirming the identification. The detection limit of HgCl$_2$ analyzed by this method, calculated as 3 times the standard deviation of seven injections near the detection limit, was 9 ng, much too high for ambient air detection of mercury compounds. Replicate injections showed a high degree of variability (relative standard deviation of 30 to 45 %). The manual syringe used for injections became permanently contaminated with HgBr$_2$ and HgCl$_2$ after use, so we expect that much of the observed variability was due to retention and interactions on the syringe walls, as well as the walls of the injection port.

To eliminate the variability created by liquid injections of these very reactive compounds, we developed the system described in Methods. We tested a number of different configurations and materials to determine the method most likely to allow for identification of Hg$^{II}$ in ambient air.
pared those results to rate constants developed from exper-

sition of HgCl$_2$ and HgCl. Wilcox and Blowers (2004) determined a theoret-

eral temperature-dependent rate constant for the decompo-

terms themselves. Others have reported that higher tem-

terature allowed the cryotrap to efficiently collect Hg

data of different materials is warranted.

3.1 System materials and temperatures

As a first step in the development of the system, we tested

C. P. Jones et al.: Detection and quantification of gas-phase oxidized mercury compounds by GC/MS 2199

Figure 3. Picograms of Hg$^{II}$ and Hg$^0$ recovered when HgBr$_2$ was

permeated into mercury-free air and passed through a 15 cm section

of 0.3 cm diameter tubing constructed of the materials indicated. Tubing

was kept at 110–115$^\circ$C, except when indicated otherwise. “Siltek” indicates stainless steel tubing coated with Siltek-brand de-

activated fused silica. Whiskers represent 95% confidence intervals.

Hotter cryotrap desorption temperatures resulted in better peak areas for HgBr$_2$ (Table 2), with a desorption temperature of 240 °C resulting in the best peak area and peak shape. Hotter desorption temperatures likely resulted in more rapid volatilization of HgBr$_2$ from the cryotrap, leading to improved peak shape.

3.3 Chromatographic columns

Of the three columns we tested for transmission of HgBr$_2$, we only observed HgBr$_2$ peaks with the Rxi-5Sil MS column or the SPB-Octyl column. We observed consistent HgBr$_2$ peaks with the Rxi-1ms column. Babko et al. (2001) observed HgCl$_2$ peaks with a low-polarity column similar to the Rxi-5Sil MS column we used (DB-5; 5 % diphenyl/95 % dimethyl polysiloxane). Olson et al. (2002) only observed Hg compound peaks when using a 30 m non-polar phase column (DB1; 100 % dimethyl polysiloxane) similar to the Rxi-1ms column we used. Olson et al. (2002) were not able to observe Hg peaks with more polar columns that had polyethylene glycol, cyanopropyl phenyl, or trifluoropropyl phases.

3.4 Hg compound detection

The permeation rate for HgBr$_2$, determined by the pyrolyzer and Tekran analyzer system, was 37 pg s$^{-1}$. After incorporating the optimizations reported above, and after further optimizing the parameters of the mass spectrometer, permeation of 22.2 ng of HgBr$_2$ resulted in a peak area of 1 788 451 and a peak height of 175 723 when the MS was operated in selected ion mode for m/z 362 (Fig. 4). The HgBr$_2$ detection limit for the optimized system in selected ion mode, calculated as 3 times the standard deviation of replicate low-concentration samples, was 90 pg. The detection limit in scan mode was 300 pg.

A small, poorly formed Hg$^0$ peak was often observed prior to Hg halide peaks in chromatograms (see m/z 202 trace in top of Fig. 4). This Hg$^0$ peak was probably the result of breakdown of Hg halides to Hg$^0$ within the chromatographic column, and its poor shape can be explained by continued breakdown as Hg halides moved through the column. The small size of the peak relative to the Hg halide peak is an indicator that Hg halide decomposition in the column was limited. Hg$^0$ chromatographic peaks during Hg halide injections were not likely the result of Hg$^0$ emitted from permeation tubes, since any Hg$^0$ emitted or formed prior to the cryotrap would have passed through the cryotrap at its typical collection temperature of 0 °C.

While Hg$^0$ was detected from Hg(NO$_3$)$_2$ and HgO-containing permeation tubes (when the cryotrap cooling temperature was lowered to −50 °C), we were unable to observe unequivocal Hg(NO$_3$)$_2$ or HgO mass spectra when analyzing the output of these permeation tubes with the GC/MS. A consistent peak with a prominent 218 m/z signal was observed at a retention time of about 10 min when Hg(NO$_3$)$_2$ or HgO was permeated (Fig. 5). While m/z 218 is the most abundant expected mass for HgO$^+$, the observed isotope pattern did not indicate Hg. Instead, the mass spectrum for this peak was similar to mass spectra for siloxanes, indicating column or tubing degradation as the source. The absence of Hg in this
peak was confirmed by the lack of an Hg$^+$ signal at $m/z$ 202 (Fig. 5).

Lyman et al. (2009) constructed HgO permeation tubes and found that, along with Hg$^0$, an Hg compound was emitted from these tubes that could be collected and analyzed using KCl-coated denuders or cation-exchange membranes. Huang et al. (2013a) showed that, when collected on nylon membranes, the Hg compound emitted from HgO permeation tubes exhibited a thermal desorption profile that was different from those exhibited by HgCl$_2$, HgBr$_2$, and Hg$^0$. They showed that Hg(NO$_3$)$_2$ permeation tubes also emit a reactive Hg compound. It is not known, however, whether the Hg compound emitted from HgO permeation tubes is HgO. Huang et al. (2013a) proposed that the emitted compound could be Hg$_2$O. Regardless of the chemical identity of the compound, it is possible that we were not able to detect it because it degraded within the system tubing, valves, or the chromatographic column. The GC/MS did not report any Hg signal, including Hg$^0$, when analyzing the output from HgO and Hg(NO$_3$)$_2$ permeation tubes with a cryotrap temperature of 0°C. This indicates either (1) the Hg compound emitted from these permeation tubes degraded prior to or within the cryotrap, allowing Hg$^0$ to pass through the cryotrap and out of the system; (2) the emitted Hg compound is too volatile to collect on a cryotrap at 0°C, or (3) the emitted Hg compound becomes permanently bound to some part of the analytical system and does not degrade. System temperatures and materials were optimized for HgBr$_2$, and different materials and/or a different temperature regime may improve detection for compounds emitted from HgO and Hg(NO$_3$)$_2$ permeation tubes.

We introduced small quantities of HgO and Hg(NO$_3$)$_2$ (separately) into the direct injection probe on the MS to determine a mass spectrum for these compounds. Figure 6 shows these mass spectra. Only Hg$^+$ was observed from the direct injection of HgO, and no significant signal was observed around $m/z$ 218 (HgO$^+$) or $m/z$ 420 (Hg$_2$O$^+$). This could be because (1) HgO is not volatile enough to produce enough vapor in the ionization chamber of the MS to result in a detectable signal, so only off-gassed Hg$^0$ was observed (as Hg$^+$) or (2) the ionization energy of the MS was so strong that all HgO was broken down to Hg$^+$ within the ionization chamber. HgO$^+$ was observed, however, when Hg(NO$_3$)$_2$ was inserted into the direct probe, probably as a breakdown product. This provides evidence that the MS could detect HgO as HgO$^+$ if it did indeed exist in the gas phase. The fact that it was not detected when solid HgO was inserted into the direct probe may indicate that HgO does not have an appreciable gas phase. If this is the case, it is not clear what is emitted from HgO permeation tubes that can be collected on nylon membranes and KCl-coated denuders (Huang et al., 2013a).

The mass spectrum for Hg(NO$_3$)$_2$ showed Hg(NO$_3$)$_2^+$ ($m/z$ 326) and several breakdown products, including HgNO$_3^+$ ($m/z$ 264), and HgO$^+$ ($m/z$ 218). A cluster of peaks around $m/z$ 343 was also observed and could be interpreted as the monohydrate of Hg(NO$_3$)$_2$. Olson et al. (2002) dissolved Hg(NO$_3$)$_2$ in acetonitrile and interpreted resultant mass spectra to be caused by reaction of Hg(NO$_3$)$_2$ with column material, producing CH$_3$HgCl. Our direct probe results suggest the existence of gas-phase Hg(NO$_3$)$_2$ and do not match the spectra presented by Olson et al. (2002).

3.5 Laboratory tests of sample collection materials

We permeated Hg compounds onto nylon membranes and into PDMS foam-filled tubes, quartz wool-filled tubes, and deactivated fused silica-coated tubes and used the sample desorption oven to transmit collected Hg compounds onto the cryotrap and then into the GC/MS. When we heated nylon membranes to 100°C or greater in the desorption oven, the prominent observed peak was consistent with dodecanedioic acid, a potential degradation product of the nylon material (Carragher, 2014). Dodecanedioic acid exhibits prominent peaks at and near $m/z$ 200, and the dodecanedioic acid peak intensity was so high as to obscure any Hg peaks when loaded in the laboratory or when sampling ambient air. Huang et al. (2013a) used nylon membranes to collect Hg compounds and desorbed those compounds into a pyrolyzer and atomic fluorescence analyzer. The atomic fluorescence instrument only detects Hg$^0$, however, so interference from nylon breakdown products was not an issue.
Like nylon membranes, PDMS foam-filled tubes also had too much interference to allow for detection of Hg compounds, even when loaded with as much as 60 ng HgBr$_2$.

Quartz wool-filled PFA tubes exhibited less interference and clearly identifiable Hg halide signals (Fig. 7). However, chromatograms from quartz wool-filled tubes had poorly shaped peaks and substantial non-Hg signal. The cause of the poorly shaped peaks is not known. Quartz particles could have accumulated in the cryotrap, causing a slow desorption of Hg compounds during cryotrap heating. If this occurred, the quartz particles were apparently cleaned out after each analysis, since we performed injections of Hg halides directly from the permeation oven onto the cryotrap subsequent to quartz wool analyses and observed normal chromatographic peaks.

While HgCl$_2$ was loaded onto a quartz wool-filled tube for the analysis shown in Fig. 7, the figure shows some HgBr$_2$ signal in the mass spectrum. The quartz wool-filled tube had previously been loaded with HgBr$_2$, and some residual HgBr$_2$ apparently remained in the tube. Additionally, a cluster of masses centered at $m/z$ 316, corresponding with HgBrCl, can be clearly observed in the mass spectrum. The same cluster of masses can be seen in part B of Fig. 2 and in Fig. 4. HgBrCl could exist because of (1) a reaction between HgCl$_2$ and HgBr$_2$ in the acetone solution in Fig. 2 or on the quartz wool in Fig. 7, or (2) it could be a contaminant in the commercial Hg halide compounds used in this study.

The deactivated fused silica-coated stainless steel tube collected HgBr$_2$ with no discernable non-Hg interference, but the amount of HgBr$_2$ collected was low, probably because of high breakthrough. Deactivated fused silica-coated tubing may be a viable HgBr$_2$ collection device if a device with larger surface area is used and/or if the tubing is cooled to a temperature that limits Hg$_{II}$ breakthrough.

### 3.6 Ambient air sample collection

The location, duration, and methods used for ambient air sample collection are given in Methods. None of the ambient air samples collected using quartz wool-filled tubes or nylon membranes resulted in any detectable Hg compounds. Low Hg$_{II}$ concentrations in ambient air could have led to a sampled Hg$_{II}$ mass below the detection limits of the GC/MS. 10.1 m$^3$ of ambient air was sampled by each nylon membrane, and 5.4 m$^3$ of air was sampled by each quartz wool-filled tube. These sampling volumes are adequate to collect 100 pg Hg$_{II}$ (within the detection limit of the GC/MS) if ambient Hg$_{II}$ was 10 and 18 pg m$^{-3}$, respectively. Not all ambient air sample collections were associated with alternative Hg$_{II}$ measurements, but for quartz wool-filled tube collection at the University of Nevada, Reno, Hg$_{II}$ (measured by a Tekran 2537/1130/1135 speciation system as the sum of Hg collected on the system’s denuder and particulate filter) was 38 ± 9 pg m$^{-3}$ (mean ±95 % confidence interval). However, some breakthrough may have occurred through the sample collection devices, and the non-Hg interference caused by the sample collection devices likely increased the actual detection limit for these samples. Alternatively, it is possible
that the Hg compounds in sampled ambient air were not Hg halides and were undetectable by the GC/MS system.

3.7 Future work

Improvements to the MS used in this work may increase its sensitivity for Hg compounds and decrease the detection limits of our system. Deeds et al. (2015) reported detection limits of 6–40 pg for HgCl₂ and HgBr₂ with an atmospheric pressure chemical ionization MS, and pointed out that chemical ionization is likely to decrease detection limits relative to electron impact ionization. The system used by Deeds et al. (2015), however, suffered from interference from non-Hg compounds found in ambient air because it did not utilize chromatographic separation. Our GC system, coupled with chemical ionization MS, may be able to achieve improved ambient air detection limits while maintaining the ability to separate individual Hg compounds and separate Hg compounds from non-Hg atmospheric constituents.

Interference in mass spectra created by collection materials likely limited our ability to detect Hg compounds in ambient air. Testing of additional collection materials is needed. Deeds et al. (2015) used shredded Teflon packed in tubes to collect Hg halides, and they did not note any interference from these materials. We found no interference from deactivated fused silica-coated stainless steel tubing. Highly inert surfaces like these are ideal because they do not result in off-gassing that may interfere with mass spectra. However, Hg(II) may not collect efficiently on these surfaces unless they are cooled to 0 °C or lower. In addition, Lyman et al. (2010b) reported that ozone reduces Hg halides collected on uncoated quartz traps to Hg⁰, and highly inert surfaces may also leave Hg(II) exposed to reaction with ozone or other atmospheric constituents.

We observed poor results from tubes packed with PDMS foam, but saw little interference from the PDMS-coated chromatographic column (for Hg halides). PDMS in chromatographic columns is cross-linked to stabilize it and is less likely to decompose. PDMS denuders have been used successfully to preconcentrate a wide variety of compounds (Burger et al., 1991; Dudek et al., 2002), including semivolatiles (Rowe and Perlinger, 2010). PDMS may also shield analytes from atmospheric oxidants that have low affinity for the PDMS phase (possibly including ozone) (Rowe and Perlinger, 2010).

While the GC/MS system in this study was able to separate and quantitatively analyze Hg halides, we have not yet shown that it can detect non-halide Hg compounds, including Hg(NO₃)₂ and HgO. HgO may not exist in the gas phase, but Hg(NO₃)₂ is likely to be non-polar, as are Hg halides (Goodsite et al., 2004), and likely can exist in the gas phase. HgBrX compounds, including HgBrOH, may exist in the atmosphere (Weiss-Penzias et al., 2015). HgBrOH, unlike HgBr₂, has an appreciable dipole moment (Goodsite et al., 2004) and may have different reactivity and volatility than HgBr₂. Our system is able to detect HgBrCl, so it could possibly identify other bromine-containing Hg compounds, but this has not been tested. System temperatures and materials may need to be optimized for individual compounds or groups of compounds. Different Hg compounds may perform better with different columns, as shown by Babko et al. (2001). Finally, replacement of VICI valves (which have Valcon rotors that may react with Hg compounds) with all-stainless steel valves that can be coated with deactivated fused silica may improve system performance for Hg compounds that are more reactive than Hg halides.

4 Summary

Identification of atmospheric Hg(II) is needed to improve understanding of Hg chemistry and biogeochemical cycling. The GC/MS-based system described here has a detection limit low enough to identify and quantify Hg halides in the ambient atmosphere, but better atmospheric sampling materials are needed to accomplish this. Work is ongoing to continue its development, including improving ambient air collection options, increasing the number of compounds it can reliably detect, and improving instrument sensitivity.
